Abstract Provenance is essential for auditing, data debugging, understanding transformations, and many additional use cases. All these use cases would benefit from provenance for transactional updates. We present a provenance model for snapshot isolation transactions extending the semiring framework with version annotations and updates. Based on this model, we present the first solution for computing the provenance of transactions. Our approach retroactively traces provenance using an audit log and time travel functionality (supported by many DBMS) without having to store any additional information. For a given transaction, we construct a reenactment query that simulates the effect of the transaction. This query returns the updated versions of relations produced by the transaction and has the same provenance as the transaction. Interestingly, such reenactment queries can be expressed in relational algebra and, thus, be executed by standard DBMS. We have implemented a prototype on top of a commercial database system and our experiments confirm that by applying novel optimizations we can efficiently compute the provenance of large transactions over large data sets and our approach results in only moderate overhead for transactions when no provenance is requested.

1 Introduction

Provenance, information about the creation process and origin of data, is critical for many applications including auditing, debugging data by tracing erroneous results back to erroneous inputs, understanding complex transformations, and as a supporting technology for integration and probabilistic databases. How to model and compute the provenance of database queries is relatively well understood. Most approaches model provenance as annotations on data (e.g., tuples) and propagate annotations to compute the annotation (provenance) of a query result. That is each tuple in the result of a query will be annotated with input tuples that are in its provenance and, depending on the provenance model that is employed, also how these tuples were combined to derive the result. Such techniques have been pioneered by systems such as Perm [17], DBNotes [5], Orchestra [22], and others. While provenance for queries is important, many use cases (e.g., auditing) would benefit from provenance for update operations. For instance, tracing a query result tuple back to its provenance in the query input is not sufficient for auditing, because this type of provenance does not explain how the query inputs were created (i.e., inserted and/or updated by past transactions). Relational databases execute updates as part of transactions and apply concurrency control techniques to guarantee ACID properties for transactions. Provenance tracking for database updates needs to take into account the idiosyncrasies of concurrency control protocols to correctly describe the origin of data. We present the first solution to this problem. Specifically, we extend an existing provenance model for queries (the semiring model) to also support transactional semantics, demonstrate how to compute provenance according to this model using a relational database, and present an implementation in our GProM system. We introduce reenactment, a novel technique for replaying (“reenacting”) a transactional history (or parts thereof) using queries. Reenactment queries enable us to retroactively compute the provenance of tuple versions produced by a transactional history using transaction time histories of relations and a log of SQL statements. Notably, our approach does not require any eager materialization of provenance during transaction execution nor any changes to the transactions themselves. Hence, we avoid paying the runtime and storage overhead of provenance computation for every transaction executed by the system. We focus on transactions executed under the snapshot isolation (SI) concurrency control protocol (used by, e.g., PostgreSQL, Oracle, and MSSQL) in this work.

Example 1.1 Consider the database shown in Figure 1a. Relation Order stores orders submitted by customers. Relation Outstanding stores outstanding payments for orders and their due dates. Relation Collection stores outstanding payments that have not been payed by the due date and, thus, went to collection. A history of transactions for this database is shown in Figure 2. Here we assume a discrete time domain Version and show for each update the version at which it was executed. Transaction $T_1$ creates two orders for customer Peter and inserts the order amounts as outstanding payments. Peter recognizes an error in the order and contacts customer service. The service operator corrects the error (Transaction $T_2$) by updating the order table but forgets to modify Peter’s outstanding payment accordingly. Some time later Peter decides to pay off his dept. Assuming that the error has been corrected, he pays $250 for his first order and $56 for his second order. This triggers transactions $T_3$ and $T_4$ which update the due amount (respectively delete outstanding amounts that have been fully payed). These transactions run a query that collects payments that are overdue and inserts them into the collections table.

Assume that the database applies the snapshot isolation concurrency control protocol. Figure 4 shows the states of the database after the commit of transactions $T_1$, $T_2$, $T_3$ and $T_4$, respectively. For convenience, we show tuple identifiers to the right of each tuple. Ignore the annotations shown on the left for now. Under snap-
Fig. 1: Running example database state after execution of each of the 4 transactions in the example history. Attribute values affected by an update are highlighted in red (■) and deleted tuples are highlighted in gray (□).

Fig. 2: Transactional history $H$ of the running example, showing version identifiers for each statement.
shot isolation each transaction $T$ operates on a private snapshot of the database that contains all tuple versions that were produced by transactions that committed before $T$ started and versions created by $T$’s own updates. This has no effect on transactions $T_1$ and $T_2$, because the execution of these transactions does not overlap with any other transaction. Transactions $T_3$ and $T_4$, however, do not see each other’s updates. These transactions both operate on the version of relation $\text{Outstanding}$ produced by Transaction $T_2$. This causes three (instead of one) collection tuples to be created (see Figure 7): Transaction $T_3$ sees a remaining balance of $\$50$ for order $\text{oid}_1$, and does not see the deletion of the outstanding payment for order $\text{oid}_2$. Transaction $T_4$, sees the previous balance of $\$300$ for order $\text{oid}_1$.

Peter, surprised to receive a letter about outstanding payments, calls the customer service again. The representative will not be able to explain why the due amounts went to collection, because the current database state (Figure 7) provides no hint at what caused the errors. A temporal database would reveal more information, e.g., showing the unmodified $\$300$ amount in the Out\[d\] relation after the commit of Transaction $T_2$. However, critical information needed to understand the problem in this example is not available since a temporal database does not reveal which tuple versions the new collection tuples have been derived from and by which operations. For example, the representative needs to understand that tuple $c_1$ was derived from the tuple version $s_1$ produced by subtracting $\$250$ from the amount of the previous version of this tuple ($s_1$). Furthermore, this previous tuple version $s_1$ was derived from tuple version $a_1$. That is the update of Transaction $T_2$ (correction of the order price) was not taken into account. If a log of executed SQL statements is available (we call this an audit log), then the user may be able to correlate the transaction time history of the database with the audit log to infer such provenance dependencies. However, for any realistically complex SQL query and realistically sized database it would not be feasible to apply this inference manually.

This example motivates the need for an approach for tracking the provenance of tuples that are updated by concurrent transactions. A provenance model for transactions would not just have to explain how tuple versions have been combined to produce new tuple versions, but also which SQL statements did create which tuple version (and how). Ideally, it should be possible to compute the provenance of any current or past tuple version without having to eagerly materialize provenance information during transaction execution. Note that in this work we do not consider provenance dependencies at the application side. For instance, consider an application that runs a query, stores the result in a client-side variable, and then uses the variable in an update statement. Detecting such dependencies requires tracking provenance of procedural programming languages which is beyond the scope of this work. While there are existing solutions for computing the provenance of updates [22,27,8], none of these approaches support transactions and these approaches are not integrated with provenance for queries. As we will demonstrate in the following, naive combinations of existing provenance models with snapshot isolation do not fulfill our desiderata for a transaction provenance model. Techniques for replaying operations (e.g., [29]) are also not directly applicable to our problem because we do not want to pay the overhead of replaying DB updates (e.g., I/O caused by writing logs and changes to disk).

The main contributions of this work are:

- We introduce the multi-version semiring model, a provenance model for queries and updates that extends the semiring annotation framework [21]. In particular, we support transactions executed using the snapshot isolation concurrency control protocol. The provenance of a tuple version in this model encodes its complete derivation history including previous tuple versions that were used to compute it and how tuple versions have been used by updates and/or queries involved in its creation.

- We present a relational encoding of our provenance model and demonstrate how to implement provenance computation for transactions by translating reenactment queries into SQL queries using time travel to access past database states. By time travel we mean the ability to access past states of a relation in queries as supported by, e.g., Oracle, IBM, and MSSQL. We

1 Readers familiar with snapshot isolation may recognize that transactions $T_3$ and $T_4$ are an instance of the write-skew problem [5], i.e., this history is not serializable.

2 If not natively supported, time travel can be implemented using triggers to maintain a transaction time history in separate history relations (e.g., see [29], Chapter 8).
use an audit log (log of executed SQL statements) to construct reenactment queries.

Our experiments demonstrate that 1) provenance computation based on reenactment is very efficient and scales to large databases, complex transactions, and large number of updates and 2) the storage and runtime overhead incurred for running transactions when time travel and audit logging is activated is tolerable and significantly smaller than the overhead incurred by eagerly computing and materializing provenance for every transaction when it is executed.

The remainder of this paper is organized as follows. Section 2 presents an overview of our system. In Section 3, we review related work and then introduce background on provenance and concurrency control in Section 4. In Section 5, we introduce the multi-version provenance model. We study reenactment in Section 6 and demonstrate how to implement reenactment as standard relational queries in Section 7. In Section 8, we discuss our implementation and optimization techniques for reenactment. We present experimental results in Section 9 and conclude in Section 10.

2 System Overview

In this section, we give an end-to-end overview of our approach for computing provenance for transactions.

2.1 Multi-version Provenance Model

Our first contribution is to introduce MV-semirings, a provenance model that extends the well-known semiring annotation framework to account for tuple derivations under transactional semantics. For any semiring $K$, we can construct an MV-semiring $K^x$. An annotation in $K^x$ is a symbolic expression over elements from $K$ recording the derivation history of a tuple. These expressions use version annotations to enclose part of the provenance of a tuple which encodes that this part of the provenance was processed by a certain update at a certain time. There is an intuitive correspondence between these version annotations and tuple versions: each version annotation wrapping the provenance of a tuple corresponds to the creation of a new tuple version. We define update operations and a snapshot isolation (SI) transactional semantics for this model.

Example 2.1 Consider the annotations on the left of each tuple in Figure 4 showing the provenance for each tuple version according to our model. For now, we will only explain the meaning of these annotations - how to compute them will be covered later. As mentioned above, the provenance of a tuple version encodes its whole derivation history - from which tuple version was that tuple version derived and by which operations. As an extension of the semiring annotation framework, our model uses variables to denote tuples in the provenance. We wrap parts of a tuple’s provenance in version annotations to denote that it was produced by a certain type of update of transaction $T$ at time $\nu$.

Transaction $T_1$. For instance, consider the annotations on the Order relation tuples in Figure 7a. The first tuple was produced by an insert (I) of transaction $T_1$ executed at time (version) 1. Note that we assign a time stamp $\nu+1$ to tuples created by an update executed at time $\nu$. We assign a fresh variable ($x_1$ in the example) to tuples created by an insert using a VALUES clause. Inserted tuples are assigned new tuple ids (id 1 shown as a superscript in the version annotation). When the transaction creating a tuple version commits then we wrap this tuple version in a commit version annotation (C). The resulting provenance expression for this tuple is $C^0_{T_1,6}(I^1_{T_1,2}(x_1))$. Transaction $T_1$ has also inserted two tuples into relation Outstanding. These tuples are the result of running queries over relation Order. We record which tuples of relation Order each of the new tuples in relation Outstanding depends on by wrapping the provenance of these Order tuples in a version annotation. For instance, the first tuple of relation Outstanding is annotated with $C^3_{T_1,6}(I^3_{T_1,2}(x_1)))$, i.e., it was produced by an insert of transaction $T_1$ executed at time 2 which used a tuple (represented by variable $x_1$) produced by the same transaction at time 1.

---

3 Name omitted due to licensing restrictions.

4 We assume that versions in the database are identified by values from a discrete time domain.
Based on the provenance annotations in Figure 1d, the service operator from our running example can explain the three tuples in the Collection relation. For instance, it is clear that the update to the Order tuple was not reflected in the corresponding Outstanding relation tuple (the provenance contains the annotation of \(\alpha_1\) before the update) which was used to create the first tuple of the Collection relation.

2.2 Provenance Filtering

For databases with long histories, a user is likely not interested in the complete derivation history of currently valid tuples. Thus, we need an approach for abstracting away unnecessary details in our provenance model. Since our model is composable we can remove irrelevant parts of a tuple’s derivation history by replacing provenance subexpressions with new variables. We demonstrate how this approach can be applied to limit the provenance to a given transaction.

Example 2.2 Assume the service operator wants to drill down into the provenance of Transaction 3. That is, she is only interested in modifications of tuples by this transaction. This is naturally achieved in our model by replacing subexpressions in the provenance with variables that represent the input tuple versions as seen by transaction 3. For instance, for tuple \(s_1\) in relation Outstanding (Figure 1d) we would replace version annotations from previous transactions \(T_1\) and \(T_2\) in the annotation \(C_{T_2,13}(U_{T_2,9}(C_{T_1,6}(I_{T_1,3}^*(I_{T_1,2}(x_1)))))\) with a plain variable \(x_3\) wrapped in the commit annotation of \(T_1\). The resulting annotation is \(C_{T_2,13}(U_{T_2,9}(C_{T_1,6}(x_3)))\). Furthermore, we would remove the second tuple by setting its annotation to 0 (a 0-annotation denotes that the tuple is not in the relation), because this tuple was not affected by Transaction 3. The resulting provenance only contains information about 3’s updates, e.g., the update of the first tuple of relation Outstanding.

2.3 Reenactment

We next prove an important fact. If we extend our query model with a new operator that creates version annotations, then any update, transaction, or (partial) history in our model can be equivalently expressed as a query, e.g., from an update \(u\) we can derive a query \(R(u)\) which returns the same database state as the original update \(u\) (if executed over the same input). We call such queries reenactment queries. A history is a potentially concurrent execution of a set of transactions, e.g., Figure 2 shows a history. We will formally define histories in Section 3.3. Note that in this paper we are focusing on reenactment of updates or single transactions only. However, we allow these transaction to be part of a larger history. The equivalence under annotated semantics between an operation and its reenactment query has several important implications: instead of computing provenance eagerly during transaction execution we retroactively compute it by running reenactment queries. Furthermore, since our model generalizes bag-semantics snapshot isolation, we can use reenactment to recreate a database state valid at a particular time by simply running a query - including database states that were only visible within one transaction.

Example 2.3 For simplicity we illustrate reenactment using SQL and standard relation query semantics. Our formal treatment of the subject in Section 3 uses an algebra of updates and queries defined for our provenance model. For instance, an SQL update \(\text{UPDATE} R \text{ SET} a = a + 1 \text{ WHERE} b = 3\) over a relation \(R(a,b)\) can be reenacted as a query that runs over the database state valid before the update. Intuitively, we compute a union between the previous versions of tuples that were not affected by the update (tuples that do not fulfill the \(\text{WHERE}\) clause condition) and the new version of tuples that were updated (fulfill the \(\text{WHERE}\) clause condition). Thus, we can reenact the update shown above as:

```
SELECT * FROM R WHERE b <> 3
UNION ALL
SELECT a + 1 AS a, b FROM R WHERE b = 3;
```

2.4 Relational Implementation using Time Travel

While our model fulfills our desiderata for a transaction provenance model, it would require major changes to implement it within a DBMS. Our third major contribution is a mapping of our provenance model to a standard relational representation and a method for using an audit log (a log of SQL statements executed on the database) to construct reenactment queries and time travel to access past database states when running reenactment queries. Thus, we can compute the provenance of past updates, transactions, and across transactions - without having to materialize any additional information, without modifying the DBMS, and without requiring changes to the transactional workload.

Example 2.4 Figure 3 shows the relational representation of the provenance of relation Collection from the example history restricted to transaction 3. The annotation of a tuple \(t\) is represented as several tuples by duplicating the tuple \(t\) and storing part of the annotation in additional attributes. Tuple variables are represented by actual tuples. Version annotations are represented as boolean attributes \((U_i \text{ for update } u_i)\) which...
are true if this part of the provenance has this version annotation and false otherwise. In Figure 3 we show the annotation encoded by a tuple on the left of this tuple. The boolean annotations $U_1$ and $U_2$ represent the version annotations for the update ($u_1$) and insert ($u_2$) of Transaction $T_3$. For instance, consider the annotation $C_{T_3,13}(I_{T_2,11}(U_{T_2,9}(x_3)))$ of tuple $t = (oid_1, 50)$ derived by replacing $C_{T_2,6}(I_{T_1,6}(I_{T_1,2}(x_1)))$, the part of the annotation of $t$ related to previous transactions, with a new variable $x_3$. This tuple was affected by both updates of $T_3$. Thus, both $U_1$ and $U_2$ are set to true. The tuple version $t' = (oid_1, 300, 2000-05)$ from relation Outstanding from which tuple $t$ was derived (represented by variable $x_3$ in the provenance annotation) is stored in additional attributes we add to the schema. Here $P$ denotes a renaming function used to distinguish attributes storing provenance from attributes storing data.

Note that while the number of attributes in the relational encoding depends on how far back provenance is traced this representation is not materialized but constructed on the fly using reenactment when a user requests provenance. Using actual tuple values to represent variables in provenance expressions is often more meaningful to a user than other representations of the variables such as pairing tuple identifies with versions. Nonetheless, we let the user decide how tuples are represented (actual values, tuple id and timestamp, or both).

2.5 GProM

We have implemented the techniques discussed above in our GProM [3] provenance middleware. GProM works as a wrapper of a standard relational database. The user interacts with the system using the SQL dialect of the underlying DBMS. We support several extensions for computing provenance which are seamlessly integrated within SQL. For example, the user can request the provenance of a query, update, or single transaction, or for a certain time interval. To process a transaction provenance request we 1) query the audit log to gather sufficient information to be able to construct a reenactment query and 2) translate the reenactment query into an SQL query with time travel (i.e., querying the transaction time history of tables) which returns our relational encoding of provenance (e.g., as shown in Figure 3). From a language point of view, a provenance request is treated as a query that returns a relational provenance encoding, e.g., it can be used as a subquery (to query provenance).

Fig. 3: Relational encoding of the provenance of example transaction $T_3$

Provenance of relational queries has been studied extensively in the recent years leading to the development of several models including Why-provenance [9]. Where-provenance [9], and Lineage [12]. See [11] for an overview. The seminal paper from Green et al. [19] introduced the $\kappa$-relational model, an extension of the relational model with annotations from a commutative semiring and has shown how such annotations propagate through positive relational algebra ($\mathcal{RA}^+$) queries. The semiring of provenance polynomials is the most general form of annotation in this model. Provenance polynomials generalize the relational datamodel (set and bag semantics), several extensions (e.g., trust), and less informative provenance models including Lineage and Why-provenance. See [21] for an overview of this model and its extensions beyond positive relational algebra (e.g., set difference [13] and aggregation [2]). Kostylev et al. [24] have studied data annotated with annotations from multiple semirings. Buneman et al. [10] relax the semiring model for a hierarchical data model where the distinction between data and annotation is flexible - allowing queries to treat part of a hierarchy as annotations and others as data. Oltenau et al. [25] discuss factorization of provenance polynomials and Amstel et al. [11] rewrite queries into equivalent queries (under set semantics) with minimal provenance. Boolean Circuits can be used to compactly represent semiring expressions [13]. It has been proven that provenance poly-

</table>
nominals can be extracted from the PI-CS [17] and Provenance Games [23] models. The latter also addresses negation. We extend the semiring framework with updates and transactional semantics. The idea of annotating parts of a provenance polynomial with function symbols was, to the best of our knowledge, first applied in the context of the Orchestra system to record applications of schema mappings [20]. The version annotations in our model were inspired by this idea. The major advances we made in developing our extension are 1) encode derivation under concurrent transactions and 2) model the visibility rules of the snapshot isolation concurrency control protocol. Our model is a strict generalization of the semiring model in the sense that we can derive the semiring annotations of a tuple from our model. As we will discuss further in Section 5, naive combinations of the semiring model with implementations of snapshot isolation which use additional attributes to store version information have the disadvantage that a tuple’s provenance may be spread over multiple relations and database versions whereas in our model it is stored in the tuple’s annotation.

3.2 Systems and Provenance for Past Operations

Systems such as DBNotes [6], Orchestra [22], Logic-Blox [21], and Perm [17] encode provenance annotations as standard relations and use query rewrite techniques to propagate these annotations during query processing. We also implement provenance computation for transactions by propagating a relational encoding of provenance annotations. Similar to the Perm system, we refrain from eagerly computing provenance for all operations, but instead reconstruct provenance when requested. Zhang et al. [25] demonstrated that an audit log and time travel functionality is sufficient for computing the provenance of past queries. In this work, we prove that audit logging and time travel are also sufficient for computing the provenance of transactions. This idea of using a log of operations (and changes to data) to reconstruct provenance by replaying operations has also been applied in the DistTape system [29] (distributed datalog) and the Ariadne system [16] (stream processing). Such replay techniques could be applied to replay SI transactional histories as long as the replay mechanism implements snapshot isolation (or alternatively enforces the visibility rules of snapshot isolation) and ensures that the operations of transactions are executed in the same order as in the original history. The novelty of our reenactment mechanism lies in the fact that instead of replaying updates we construct a reenactment query that simulates the updates. The execution order of operations in the history is “hard-coded” into that query. Thus, we do not have to pay the overhead of DB update operations (caused by logging, concurrency control, and I/O of writing changes to disk) and can apply optimizations such as reordering updates and pushing selections through updates that are not available to a DBMS if the system replays updates one at a time.

3.3 Provenance for Updates

Provenance for updates has been studied in related work [22, 23, 27], but none of these approaches addresses the complications that arise when updates are run as parts of concurrent transactions. Note that the “transactions” from Archer et al. [4] are sequences of updates and not concurrent transactions. Buneman et al. [7] present a copy-based model of provenance for curated databases where sequences of updates are grouped into transactions to reduce the size of provenance at the cost of losing information about intermediate states produced by updates. This work also did not consider concurrent transactions. Buneman et al. [8] have studied a copy-based provenance type for the nested update language and nested relational calculus. Vansummeren et al. [27] define provenance for SQL DML statements by modifying the updates to store provenance. Our approach differs in that we reconstruct provenance on demand instead of computing and storing provenance for all operations. Furthermore, we are the first to compute transactional provenance (for the snapshot isolation [5] concurrency control protocol) using a novel technique for query-based replay (reenactment). Extending approaches for updates to support transactions is non-trivial, because it requires tracking provenance through multiple operations taking the visibility of tuple versions into account (some of which only exist temporarily during the execution of a transaction).

4 Background

In this section we introduce necessary background on concurrency control and semiring annotated data.

Snapshot Isolation. Under Snapshot isolation (SI) [5] each transaction T sees a private snapshot of the database containing changes of transactions that have committed before T started and T’s own changes. Using SI, reads never block concurrent reads or writes, because each transaction sees a consistent database version as of its start. To support snapshots, old tuple versions cannot be deleted until all transactions that may need them have finished. Typically, this is implemented by storing multiple timestamped versions of each tuple and
assigning a timestamp to every transaction when it begins that determines which version of the database it will see (its snapshot). Concurrent writes are allowed under SI. However, if several concurrent transactions write the same data item \( d \), only one will be allowed to commit. Under the First Committer Wins (FCW) rule, the transaction which tries to commit first is allowed to commit. Under the First Updater Wins (FUW) rule, the first transaction updating \( d \) is allowed to commit. SI corresponds to isolation level SERIALIZE in systems such as Oracle and older versions of PostgreSQL. These implementations neither apply the FCW nor the FUW rule, but instead use write locks that are held until transaction commit. A transaction \( T \) waiting for a lock is aborted if the transaction \( T' \) holding the lock commits (and continues if \( T' \) aborts).

The Semiring-Annotation Framework. Green et al. \[19,21\] have introduced the semiring annotation framework. In this framework \[21\] relations are annotated with elements from a commutative semiring \( K = (K, +, \times, 0_K, 1_K) \). Such relations are called \( K \)-relations. Formally, a \( K \)-relation \( R \) is a (total) function that maps tuples to elements from \( K \) with the convention that tuples mapped to \( 0_K \), the 0 element of the semiring, are not in the relation. The operators of the positive relational algebra \( (R, A^+) \) over \( K \)-relations are defined by applying the \( +_K \) and \( \times_K \) operations of the semiring to input annotations. \( K \)-relations generalize extensions of the relational model including bag semantics, incomplete databases, and various provenance models (e.g., Lineage). Intuitively, the \( +_K \) and \( \times_K \) operations of the semiring correspond to alternative and conjunctive use of tuples. For instance, if an output tuple \( t \) was produced by joining input tuples annotated with \( k \) and \( k' \), then the tuple \( t \) would be annotated with \( k \times_K k' \). Provenance polynomials (semiring \( \mathbb{N}[X] \)) polynomials over a set of variables \( X \) which represent tuples in the database, are the most general form of semiring annotation. Using \( \mathbb{N}[X] \), every tuple in an instance is annotated with a unique variable \( x \in X \). This semiring \( \mathbb{N}[X] \) has the important property that for any semiring \( \mathcal{K} \) the annotation of a query result \( t \in \mathcal{K} \) can be derived from the provenance polynomial for \( t \). This is done by mapping each elementary operation \( x \in X \) to an element from \( \mathcal{K} \) and interpreting the abstract \( + \) and \( \times \) operations in \( \mathbb{N}[X] \) as the corresponding operations in \( \mathcal{K} \). Formally, any valuation \( \chi : X \to \mathcal{K} \) of variables to elements from a semiring \( \mathcal{K} \) can be lifted to a semiring homomorphism \( \text{Eval}_\chi : \mathbb{N}[X] \to \mathcal{K} \). Semiring homomorphisms commute with queries. The table below shows some semirings and the extensions of the relational model they encode.

<table>
<thead>
<tr>
<th>Semiring</th>
<th>Corresponding Model</th>
</tr>
</thead>
<tbody>
<tr>
<td>((\mathbb{B}, \lor, \land, \text{false}, \text{true}))</td>
<td>Set semantics</td>
</tr>
<tr>
<td>((\mathbb{N}[+],+,\times,0,1))</td>
<td>Bag semantics</td>
</tr>
<tr>
<td>((\mathbb{P}(X)\cup{\bot},\cup,\land,\bot,\emptyset))</td>
<td>Lineage</td>
</tr>
<tr>
<td>((\mathbb{N}[X],+,-,0,1))</td>
<td>Provenance polynomials</td>
</tr>
</tbody>
</table>

The semiring \( \mathbb{B} \) with elements \text{true} and \text{false} using \( \lor \) as addition and \( \land \) as multiplication corresponds to set semantics. The semiring \( \mathbb{N} \), the set of natural numbers with standard arithmetics corresponds to bag semantics. In the Lineage provenance model, the provenance of a result tuple \( t \) of a query is a set of tuples from the input that were used to derive \( t \). The semiring over the powerset of tuples in an instance (represented as variables \( X \)) using set union for addition and multiplication corresponds to Lineage \[11\].

Example 4.1 Consider the \( \mathbb{N}[X] \)-relation \( R_f \) shown below and the result of evaluating the query \( Q = \Pi_A(\ R_f \bowtie \mathcal{P}(\ R_f)) \) (persons that have friends with friends) over this relation. The provenance polynomial for the query result tuple records that this tuple was produced by joining \( x_1 \) with \( x_2 \) \((x_1 \times x_2)\) and by joining \( x_1 \) with \( x_3 \) \((x_1 \times x_3)\). By mapping \( x_1, x_2, \) and \( x_3 \) to \text{true} and interpreting \( + \) as \( \lor \) and \( \times \) as \( \land \) we get a \( \mathbb{B} \)-annotation true indicating that the result tuple exists under set semantics. By mapping \( x_1 \) to \( x_3 \) to \( 1 \in \mathbb{N} \) and evaluating the resulting expression we get \( 1 \times 1 + 1 \times 1 = 2 \), the multiplicity of the tuple under bag semantics. Finally, by mapping \( x_i \) to \( \{x_i\} \) for \( i \in \{1,2,3\} \), and by interpreting the expression in the lineage semiring we get \( \{x_1,x_2,x_3\} \), the Lineage of the result.

5 Multi-Version Provenance Model

We need a provenance model which is powerful enough to provide a full account of how tuple versions have been derived from other tuple versions and through updates in an SI history. A typical way of implementing SI (and transaction time databases in general) is to store multiple versions of each tuple in a relation and use additional attributes which are hidden from the user to store a unique tuple identifier, the time interval during which the tuple version was valid, and potentially the transaction which created the tuple version. Each update of a tuple creates a new tuple version with the same tuple identifier, the start time set to the current

\[5\] \(\bot\) means not in the database and \(\emptyset\) means no provenance. \(\cup\) and \(\times\) are both set union except for \(\bot\) where these operations are defined as \(k \cup \bot \bot = k\) and \(k \times \bot \bot = \bot\).
time, the end time set to UC (until changed), and the transaction identifier set to the transaction updating the tuple. Such an update would also set the end time of the previous version of this tuple to the current time.

It is tempting to extend such a representation of snapshots with semiring annotations to represent provenance for snapshot isolation histories. However, we will demonstrate in the following that this approach has two major drawbacks: 1) the derivation history of a tuple is not fully contained in the tuple’s annotation in this representation. In fact, tracing the origins of a tuple requires correlating annotations from multiple tuple versions - possibly across relations and several versions of the database; 2) even if we combine information from multiple tuple versions it may not be possible to reconstruct a tuple’s complete derivation history.

**Example 5.1** As an example of the first problem consider how the instance of Figure 1a would be represented using K-relations and a typical implementation of snapshot isolation using three additional attributes: the identifier of the transaction that created the tuple version (XID), the version when the tuple started to be valid (T_b), and the version when this tuple version is no longer valid (T_e). We show this instance below. Attribute T_b of tuple t is set to the commit time of the transaction that produced tuple t. Using this technique to store snapshot relations, the tuple versions visible to an update within a transaction T include all tuples committed before T started that were still valid when T started (T_b ≤ Start(T) < T_e) plus all of T’s own changes (XID = T).

</tbody>
</table>

The first difference of this representation to the instance annotated using our model is that the annotations of the tuples in relation Outstanding do not contain the whole provenance of such a tuple - part of its provenance is stored in a tuple from the Order relation. Thus, reconstructing the complete derivation history of a tuple requires correlating provenance across multiple tuples. Compared to the instance in Figure 1a, we have lost information of how tuples have been derived, e.g., although we can infer that the two tuples annotated with x_1 are somewhat related, we do not know how. All we know is that they were both produced by Transaction T_1 and started to be valid at time 5 (the time when T_1 committed). Extending the model by adding additional attributes such as tuple identifiers and identifiers for the update operation creating a tuple would solve this problem for this particular example. However, this not true in the general case. Consider a relation R(A, B, C) : \{(1, 2, 3) \rightarrow x\} (here we denote a tuple t annotated with k as t \rightarrow k) and an insert

```
INSERT INTO S (SELECT A,C FROM R UNION SELECT B,C FROM R)
```

This creates the following instance S(A,C) : \{(1, 3) \rightarrow x, (2, 3) \rightarrow x\}. The same transaction then executes an insert

```
INSERT INTO T (SELECT C FROM S WHERE ε(A))
```

where function f’s return type is boolean. Let us assume that f(1) = true and f(2) = false. The new tuple t_{new} = (3) inserted into table T will be annotated with x. Based on this annotation it is impossible to know whether this tuple was derived from tuple (1, 3) or (2, 3). Additional information that we can extract from the temporal attributes of the snapshot isolation implementation is not useful for resolving this ambiguity.

These examples illustrate the need for a provenance model that can help us track the origin of tuple versions. We have developed an extension of the semiring model that fulfills this requirement. Given a semiring K, we construct a new semiring K' that represents K with embedded history. We call structures constructed in this fashion multi-version (MV) semirings. The elements of such a semiring are symbolic expressions over elements from K, version annotations, and semiring operations where the structure of an expression encodes the derivation history of a tuple. Recall from Example 1.3 that version annotations wrap a part of the provenance to indicate that a version of a tuple with identifier id (with the wrapped provenance) was modified by a certain type of update operation (Insert, Update, or Delete), executed as part of a transaction T, at time \( \nu - 1 \). Furthermore, we use a version annotation C to denote that the transaction T creating a tuple version committed at time \( \nu - 1 \) and, thus, the tuple version will be visible to transaction starting at or after \( \nu \). The symbolic expressions that are the elements of an MV-semiring are uninterpreted with the exception of a set of equivalence relations which ensures that K defines the laws of commutative semirings and addition as well as multiplication with operands from K can be evaluated.

**Definition 5.1** Let \( T \) be a domain of transaction identifiers, \( V \) a domain of version identifiers, \( \Lambda \) a domain of tuple identifiers, and \( K = (K^+, K \times \Lambda, 0_K, 1_K) \) a commutative semiring. The set \( \Lambda \) of version annotations contains the following elements for each transaction \( T \in T \), version \( \nu \in V \), and tuple identifier \( id \in \Lambda \): \( T_{\nu,v}^a, T_{\nu,v}^d, D_{\nu,v}^a, C_{\nu,v}^a \). Consider the set of finite symbolic expressions \( P \) defined by the grammar shown below where \( k \in K \) and \( A \in K \).

\[
P := k \mid P + P \mid P \times P \mid P 
\]
Laws of commutative semirings

\[ k \cdot 0 = 0 \quad k \cdot 1 = k \quad (\text{neutral elements}) \]

\[ k \cdot k' = k' \cdot k \quad (\text{commutativity}) \]

\[ k \cdot (k' + k'') = (k + k') \cdot k'' \quad (\text{associativity}) \]

\[ k \cdot 0_k = 0_k \quad (\text{annihilation through 0}) \]

\[ k \cdot (k' + k'') = (k \cdot k') + (k \cdot k'') \quad (\text{distributivity}) \]

**Evaluation of expressions with operands from \( K \)**

\[ k + k' = k + k' \quad k \times k' = k \times k' \quad (\text{if } k \in K \land k' \in K) \]

**Equivalences involving version annotations**

\[ \mathcal{A}(0_k) = 0_k \quad \mathcal{A}(k + k') = \mathcal{A}(k) + \mathcal{A}(k') \]

Fig. 4: Equivalence relations for \( K' \)

\[ \mathcal{A}(P). \text{ Furthermore, let } K' \text{ be the set of congruence classes for expressions in } P \text{ based on the equivalence relations shown in Figure 4. We use } [k], \text{ to denote the congruence class of } k \in P. \text{ The multiversion semiring (MV-semiring) for semiring } K \text{ is the structure } K' = ([k]_\sim)_{k \in K}. \text{ Here } \times_{K'} \text{ is defined as } [k]_\sim \times_{K'} [k']_\sim = [k \times k']_\sim. \text{ Operation } +_{K'} \text{ is defined analogously.} \]

Note that the structure \( K' \) is a semiring. The elements of this structure are expressions build from version annotations, elements from \( K \), and the operations \( + \) and \( \times \). In such expressions we are allowed to evaluate products and sums that only combine elements from \( K \), but not allowed to interpret version annotations except for applying the equivalences used in the construction. For example, \( k = U_{10}^{15} + 5 \) is a valid element of \( \mathbb{N}^+ \), the bag semantics MV-semiring, which denotes that a tuple with tuple identifier 1 was produced by an update (U) of transaction 10 at version 5. This element \( k \) is in the same equivalence class as \( U_{15}^{10} \) based on the equivalence that enables evaluation of addition over elements from \( K \). The intuitive meaning of the equivalence for version annotations are: 1) update operations never create tuples from non-existing or deleted tuples (recall that if a tuple is annotated with \( 0_k \) in relation \( R \) this denotes that the tuple is not in the relation \( R \)) and 2) alternative use of tuples distributes over updates (e.g., updating the result of a union query returns the same result as computing the union after updating its inputs). In the following we will omit the subscript of operations and neutral elements if the semiring is clear from the context or irrelevant to the discussion. Since we typically define a single semiring structure for a given set \( K \), we will sometimes use \( K \) to refer both to the semiring \( K \) and its set \( K \) interchangeably.

**Definition 5.2** Let \( \mathbb{D} \) be a universal domain of values and \( K \) a semiring. An \( n \)-ary \( K \)-relation \( R \) is a function: \( \mathbb{D}^n \rightarrow K \) that maps each tuple \( t \in \mathbb{D}^n \) to an annotation from \( K \). We require that \( R \) has finite support (number of tuples not mapped to 0). A \( K \)-database is a set of \( K \)-relations.

There exists a strong connection between \( K \) and \( K' \) relations: By evaluating the symbolic expression that make up an \( K' \) element interpreting version annotations as functions \( K \rightarrow K' \), we transform an \( K' \) relation into a corresponding \( K \) relation. Conceptually, this means we are removing the embedded history from the provenance. For example, if we apply this approach to derive provenance polynomials from their \( K' \) counterpart, the result will record from which tuples a tuple was derived (and how), but no longer encode its update history. Below we define an operator \( \mathcal{U}v \) that implements this mapping based on a function \( h_U : K' \rightarrow K \).

In Section 5.2 we will prove that \( h_U \) is a semiring homomorphism which as proven by Greene et al. [10] implies that it commutes with queries.

**Definition 5.3** Let \( R \) be a \( K' \)-relation. The unversioning operation \( \mathcal{U}v(R) \): \( K' \)-relation \( \rightarrow K \)-relation applies the mapping \( h_U : K' \rightarrow K \) defined below to every tuple’s annotation, i.e., \( \mathcal{U}v(R)(t) = h_U(R(t)) \).

\[ h_U(k') = \begin{cases} k & \text{if } k \in K \setminus [k]_{\sim} \\
I(U_{10}^{15}(k'))/U_{10}^{15}(k') & \text{if } k = I(U_{10}^{15}(k'))/U_{10}^{15}(k') \setminus [k]_{\sim} \\
0 & \text{if } k = 0 \end{cases} \]

Note that we use \( k = I(U_{10}^{15}(k'))/U_{10}^{15}(k') \) as a notational shorthand for \( k = I(U_{10}^{15}(k')) \) unless \( k = 0 \) and will use similar notation throughout the paper, e.g., \( I(U) \) denotes a version annotation that is either an insert or update. The application of \( \mathcal{U}v \) to an \( K' \)-database \( D \) is defined in the obvious way.

**Example 5.2** Reconsider the instance of relation **Outstanding** from the example shown in Figure 14. This instance is annotated with \( \mathbb{N}[X]^\prime \), the MV version of the provenance polynomial semiring. The first tuple \( s_2' \) is annotated with \( C_{21,13}^2(U_{21,9}(I_{21,5}^3(I_{21,2}(x_1)))) \), i.e., it was created by an update of Transaction 3, that updated a tuple inserted by \( T_1 \) based on another previously inserted tuple by the same transaction. Based on the outermost commit annotation we know that this tuple version is visible to transactions starting after version 12. The second tuple \( s_2' \) is annotated with \( C_{21,13}^2(D_{10,10}(C_{21,6}(I_{21,5}^3(I_{21,2}(x_1))))) \), i.e., this tuple was deleted by Transaction 4, and was originally produced by
a sequence of two inserts by Transaction $T_1$). If we apply Unv to relation Outstanding, then $s'_1$ is annotated with $x_1$ and $s'_2$ is annotated with 0 (indicating that the deleted tuple $s'_2$ is not in the instance).

In the following we make use of a normal form for $K^\nu$ elements that represents them as a sum of subexpressions which use multiplication and version annotations. This will simplify the definition of updates and transactional semantics in our model.

**Definition 5.4** An $K^\nu$ element $k$ is normalized if it is of the form: $\sum_{i=0}^{n} k_i$ where 1) none of the summands $k_i$ contains addition and 2) all summands are non-zero.

Note that any annotation $k$ can be translated into this normal form by applying the equational laws of MV-semirings. For example, an annotation $I^2_{T,\nu}(U^2_{T,\nu}(x_1)) + I^2_{T,\nu}(U^2_{T,\nu}(x_2))$ can be normalized based on distributivity of addition over version annotations into $I^2_{T,\nu}(U^2_{T,\nu}(x_1)) + I^2_{T,\nu}(U^2_{T,\nu}(x_2))$. In the following, it will be helpful to introduce notation for accessing particular elements from the sum of a normalized $K^\nu$ element. We use $n(k)$ to denote the number of summands of a normalized $K^\nu$-element $k$ and $k[i]$ to denote the $i^{th}$ element in the sum (assuming some order over the summands).

### 5.1 Queries

We use the standard definition of positive relational algebra $(\mathcal{RA}^+)$ over $K$-relations with the exception that we add one operator $\{ t \rightarrow k \}$ that creates a singleton relation containing the tuple $t$ annotated with $k$. Note that this is an extension of the empty relation operator introduced in the original work on $K$-relations [10]. For sake of completeness, we repeat the full definition of $\mathcal{RA}^+$ here. We use $t.A$ to denote the projection of a tuple $t$ on a list of projection expressions $A$ and $t[R]$ to denote the projection of a tuple $t$ on the attributes of relation $R$. For a condition $\theta$ and tuple $t$, $\theta(t)$ denotes a function that returns $1_K$ if $t \models \theta$ and $0_K$ otherwise.

**Definition 5.5** Let $K$ be a semiring, $R, S$ denote $K$-relations, $\text{Sch}(R)$ denote the schema of relation $R$, $t, u$ denote tuples, and $k \in K$. The positive relational algebra $\mathcal{RA}^+$ on $K$-relations is defined as:

$$P_A(R)(t) = \sum_{u : u.A = t} R(u) \quad (R \cup S)(t) = R(t) + S(t)$$

$$\sigma_{\theta}(R)(t) = R(t) \times \theta(t) \quad \{ t' \rightarrow k \}(t) = \begin{cases} k & \text{if } t = t' \\ 0_K & \text{else} \end{cases}$$

$$(R \bowtie S)(t) = R(t[R]) \times S(t[S])$$

(for any $\text{Sch}(R) \cup \text{Sch}(S)$ tuple $t$)

Note that the singleton construction $\{ t \rightarrow k \}$ introduced above does not affect the commutativity of semiring homomorphisms with queries. However, since this operator explicitly mentions a semiring element $k \in K$, a homomorphism $h : K \rightarrow K'$ has to be applied to the query too to guarantee that it returns a $K'$ relation (this is similar to the treatment of the constant annotation operator in [14]). Let $h(Q)$ denote the application of the homomorphism $h$ to query $Q$, i.e., we replace every operator $\{ t \rightarrow k \} \in Q$ with $\{ t \rightarrow h(k) \}$.

**Theorem 5.1** Let $h : K \rightarrow K'$ be a semiring homomorphism, then $h$ commutes with any $Q$ in the above algebra if $h$ is applied to $Q$. Let $I$ be a $K$ database instance. Then, $h(Q)(h(I)) = h(Q(I))$.

**Proof** The proofs to all theorems presented in this report are given Appendix.

The mapping $h_U : K^\nu \rightarrow K$ used in the definition of the UNV operator introduced above is a semiring homomorphism. Thus, the application of UNV commutes with queries. Practically, this means that we can execute queries over relations with embedded history and then derive the corresponding relation without history or equivalently strip the history information upfront.

**Theorem 5.2** $h_U$ is a surjective semiring homomorphism.

Consider $N[X]^\nu$, i.e., the MV-semiring version of the provenance polynomials semiring $N[X]$. A variation of the fundamental property of the semiring framework still holds for $K^\nu$-relations. That is, $N[X]^\nu$ generalizes all other $K^\nu$ semirings if we consider mappings that preserve embedded history. Any assignment $\chi : X \rightarrow K$ of elements from $K$ to each variable from $X$ extends to a homomorphism from Eval$_\nu : N[X]^\nu \rightarrow K^\nu$. Practically, this means that we can use the result of a query in $N[X]^\nu$ to derive the query result in any MV-semiring $K^\nu$ (and, thus also semiring $K$ by applying UNV). In fact, we prove a more general result: any homomorphism $h : K_1 \rightarrow K_2$ can be lifted to a homomorphism $h^\nu : K_1^\nu \rightarrow K_2^\nu$ by applying $h$ to each element from $K_1$ in an expression in $K_1^\nu$. We call this type of homomorphisms history-preserving because they do not change the embedded history (structure of the symbolic expression) of an MV-semiring element.

**Theorem 5.3** Any semiring homomorphism $h : K_1 \rightarrow K_2$ can be lifted to a homomorphism $h^\nu : K_1^\nu \rightarrow K_2^\nu$ as defined below. If $h$ is surjective then so is $h^\nu$.

$$h^\nu(k) = \begin{cases} h(k) & \text{if } k \in K_1 \\ A(h^\nu(k')) & \text{if } k = A(k') \\ h^\nu(k_1) + h^\nu(k_2) & \text{if } k = k_1 + k_2 \\ h^\nu(k_1) \times h^\nu(k_2) & \text{if } k = k_1 \times k_2 \end{cases}$$
Example 5.3 Consider a query $Q = \Pi_{\text{customer}}(\text{Order})$ run over the instance from Figure 12. This query returns a single tuple $t = (\text{Peter})$ as shown below. The annotation of this tuple records that $t$ was produced from two tuples in the input of the query and how these two tuples were created (e.g., $C^1_{T_{\text{customer}}} \cdot 6(I_{T_{\text{Order}}}(x_2))$). To compute the answer to this query under bag semantics, we first apply the UNV operator which returns annotation $x_1 + x_2$ for tuple $t$ and then apply an assignment $\mathbb{N}[X] \rightarrow \mathbb{N}$. If we assume that both input tuples have multiplicity 1, then tuple $t$ will be annotated with $1 + 1 = 2$, the multiplicity of this query result under bag semantics.

\[
C^1_{T_{\text{customer}}} \cdot 6(U^1_{T_{\text{Order}}}(C^1_{T_{\text{Order}}} \cdot 6(I_{T_{\text{Order}}}(x_1)))) + C^2_{T_{\text{Order}}} \cdot 4(I_{T_{\text{Order}}}(x_2))
\]

5.2 Update Operations

So far in our treatment of MV-relations we have considered instances annotated with arbitrary elements from a semiring $K^\nu$, i.e., elements that can be constructed using the grammar shown in Definition 5.1. However, not every such element can be the result of a sequence of update operations or transactional history. For example, $k = U^1_{T_{\text{customer}}} \cdot 2(C^1_{T_{\text{customer}}} \cdot 2(x))$ is a valid $\mathbb{N}[X]^\nu$ element. Nonetheless, $k$ cannot occur in a database created by a valid history because according to $k$, Transaction $T$ did update a tuple after its commit. We define admissible MV-relations (databases) as instances that can be created from an empty relation (database) by a sequence of updates or a transactional history in our model.

Definition 5.6 An $K^\nu$-relation $R$ is called admissible if there exists a (potentially empty) sequence of update operations (as defined in Definition 4.4) that if applied to an empty input produces $R$ or if there exists a history $H$ such that $R$ is a relation in the database state produced by $H$ (as defined in Definition 5.9).

We now define an update language for $K^\nu$-relations. We restrict the application of update operations to admissible instances to ensure that the input of the update has sufficient history embedded to correctly evaluate the update. In particular, summands in a normalized annotation in an admissible instance are of the form $A(k)$ and we will use this fact in the definition of update operations. In contrast to queries which do not manipulate version annotations in $K^\nu$ expressions, update operations add new versions annotations, i.e., they extend the history embedded in an $K^\nu$ annotation to record the application of the update. We introduce three update operations and a commit operation for our model. For each operation, we consider it to be executed at a time $\nu$ as part of a transaction $T$. Update operations take as input a normalized $K^\nu$-relation $R$ and return the updated version of this $K^\nu$-relation (recall that any $K^\nu$-relation can be brought into normal form). An insert $I[Q, T, \nu](R)$ inserts the result of query $Q$ into relation $R$. Note that this operation can express SQL style INSERT ... VALUES (…) (singleton operator) and INSERT ... SELECT (…) statements. Newly inserted tuples are wrapped in version annotations and are assigned a fresh tuple id ($i_{\text{new}}$). Note that we do not allow inserts to “forge” history. That is, if the query $Q$ of an insert contains a singleton operator $\{ t \rightarrow k \}$ then $k$ should be an element of the embedded semiring and not contain any version annotations. An update operation $U[\theta, A, T, \nu](R)$ modifies each tuple in $R$ that matches condition $\theta$ by applying the projection expressions in $A$. These tuples will be wrapped in version annotations. A deletion $D[\theta, T, \nu](R)$ wraps all tuples matching the condition $\theta$ in a delete annotation. Recall that UNV interprets delete annotations as functions mapping every input to 0. Thus, deleted tuples are removed when $R$ is mapped to the corresponding $K$-relation. A commit operation $C[T, \nu](R)$ wraps every input affected by transaction $T$ into a commit annotation.

Definition 5.7 Let $R$ be an admissible $K^\nu$-relation. We use $\nu(u)$ to denote the version (time) when an update $u$ was executed and $id(k)$ to denote the id of the outermost version annotation of $k \in K^\nu$. Let $A$ be a list of projection expressions with the same arity as $R$, and $i_{\text{new}}$ to denote a fresh id that is deterministically created as discussed below. Let $Q$ be a query such that for every $\{ t \rightarrow k \}$ operation in $Q$ we have $k \in K$. The update operations on $K^\nu$-relations are defined as:

\[
U[\theta, A, T, \nu](R)(t) = R(t) \times (\neg \theta(t)) + \sum_{u : u.A = t} \sum_{i = 0}^{n(R(u))} U^{id}(u)[i] \cdot \sum_{t} \times \theta(u)
\]

\[
I[Q, T, \nu](R)(t) = R(t) + \sum_{t} \times \theta(t)
\]

\[
D[\theta, T, \nu](R)(t) = R(t) \times (\neg \theta(t)) + \sum_{i = 0}^{n(R(t))} D^{id}(R(t))[i] \cdot \sum_{t} \times \theta(t)
\]

\[
C[T, \nu](R)(t) = \sum_{i = 0}^{n(R(t))} \text{COM}[T, \nu](R(t))[i]
\]

\[
\text{COM}[T, \nu](k) = \begin{cases} 
C^{id}(T, \nu + 1)(k) & \text{if } k = I[U, D^{id}(T, \nu)(k')] \\
1 & \text{else}
\end{cases}
\]
Note that for updates we will often only explicitly state the projection expressions for attributes that are updated and assume that other attributes are kept unmodified. For instance, for an update over a relation \( R(a, b, c) \) we may write \((b + 5 \rightarrow b)\) instead of \((a, b + 5 \rightarrow b, c)\). What tuple identifiers are assigned by inserts to new tuples is immaterial to our approach. However, identifiers should be assigned deterministically (to ensure that they can be recreated during reexecution as will be explained in Section 6) and should be “unique enough” to enable elements in the provenance to be distinguished (as illustrated in Example 5.1). We use a skolem function \( f_{id}(T, \nu, t, k) \) to assign new ids \( id_{new} \) that takes as input the transaction \( T \), version \( \nu \), tuple \( t \) to be annotated, and \( \mathcal{K}^{\nu} \)-element \( k \) that is wrapped in the version annotation.

**Example 5.4** Consider the update operation of Transaction \( T_2 \) from the running example. This update runs over the version of relation \( \text{Order} \) shown in Figure 14. We abbreviate the attributes of this relation as \( d \) (id), \( c \) (customer), and \( p \) (price). This update operation can be expressed in our model as:

\[
U[d = 1, p \rightarrow 250, T_2, 6](\text{Order})
\]

Tuple \( o_1 \): Tuple \( o_1 \) in the instance of relation \( \text{Order} \) is annotated with \( C^{1}_{T_2, 0}(I^{1}_{T_2, 2}(x_1)) \). This tuple fulfills the condition \( d = 1 \) of the update and, thus, the first expression \( R(t) \times (\neg \theta(t)) \) in the annotation created by the update evaluates to: \( \text{Order}(o_1) \times (\neg (d = 1)))(o_1) = C^{1}_{T_2, 0}(I^{1}_{T_2, 2}(x_1)) \times 0 = 0 \). Note that here we use concrete tuple identifiers instead of the \( f_{id} \) scheme. The second part of the expression sums the annotations over all tuples \( u \) such that if the update is applied to them the resulting updated tuples are equal to \( o_1 \). Since the update sets attribute price to a constant value, these are all tuples \((oid_1, \text{Peter}, p')\) for some price \( p' \). However, all tuples except for \( o_1 \) and \( o_2 \) are annotated with 0 in the input (they are not part of this instance). For tuples \( u \) with \( \text{Order}(u) = 0 \) the inner sum evaluates to \( U^{1}_{T_2, 0}(\text{Order}(u)) \times \theta(u) = U^{1}_{T_2, 7}(0) \times \theta(u) = 0 \). Intuitively, this is the expected result, because an update is only creating new versions of existing tuples. Tuple \( o_2 \) is annotated \( C^{2}_{T_2, 0}(I^{2}_{T_2, 4}(x_2)) \) in the input, a single element sum. Since, this tuple does not fulfill the update's condition, the inner sum evaluates to \( U^{2}_{T_2, 7}(C^{2}_{T_2, 0}(I^{2}_{T_2, 4}(x_2))) \times (d = 1))(o_2) = U^{2}_{T_2, 7}(C^{2}_{T_2, 0}(I^{2}_{T_2, 4}(x_2))) \times 0 = 0 \). Finally, \( o_1 \) is the only tuple which fulfills the condition of the update and is not annotated with 0 in the input. For \( o_1 \) the inner sum evaluates to \( U^{1}_{T_2, 7}(C^{1}_{T_2, 0}(I^{1}_{T_2, 2}(x_1))) \times (d = 1))(o_1) = U^{1}_{T_2, 7}(C^{1}_{T_2, 0}(I^{1}_{T_2, 2}(x_1))) \). As expected the annotation denotes that the resulting tuple was derived from tuple \( o_1 \) in the previous version of relation \( \text{Order} \) and was not affected by any other input tuple.

Notably, the fundamental property of \( \mathbb{N}[X]^{\nu} \), the MV-semiring of provenance polynomials, extends to updates. Recall that any valuation \( \chi : X \rightarrow K \) can be lifted to a history-preserving homomorphism \( \text{Eval}_{\chi}^{\nu} \) and the following theorem states that such lifted homomorphisms commute with updates. Note that the identifier generation scheme we have introduced for inserts uses an element \( k \) of \( \mathcal{K}^{\nu} \) as one argument of the skolem function \( f_{id} \). We extend lifted homomorphisms to also manipulate the arguments of this skolem function to ensure that they commute with updates. In particular \( h^{\nu}(f_{id}(T, \nu, t, k)) \).

**Theorem 5.4** Let \( h^{\nu} \) be a lifted homomorphism as defined in Theorem 5.3. \( h^{\nu} \) commutes with updates.

### 5.3 Transactions and Histories

We now define transactional histories for \( \mathcal{K}^{\nu} \)-databases under SI. We will limit the discussion to histories that start from an empty database. The results naturally extend to histories that are applied to any admissible \( \mathcal{K}^{\nu} \)-database. We model transactions as sequences of update operations. Note that we do not consider transaction aborts and partially executed transactions, because this is unnecessary for the purpose of retroactively computing the provenance of transactions.

**Definition 5.8** A transaction \( T = u_1, \ldots, u_n, c \) is a sequence of updates followed by a commit operation \( c \).

We use \( \text{Start}(T) \) to denote \( \nu(u) \) where \( u \) is the first update in \( T \). Similarly, \( \text{End}(T) \) denotes the commit time of transaction \( T \). A history \( H = \{T_1, \ldots, T_n\} \) over a database \( D \) is a set of transactions over \( D \) such that \( <\nu>: \{(u_i, u_j) | \nu(u_i) < \nu(u_j)\} \) is a total order.

Recall that updates are explicitly part of a transaction in our model and we record when \( \nu \) an update has been executed. This will allow us to determine the state of the database seen by each update of a transaction.

### 5.4 Historic Databases

An important property of histories in our model is that they completely determine what we refer to as a historic database. A historic database \( D_H \) for a history \( H \) executed under SI encodes the versions of \( D \) seen at each point in time by transactions from the history. Each transaction under SI sees a private version of the database. Our definition of a historical database takes this property of SI into account by defining transaction specific versions of each relation - \( R[T, \nu] \) denotes relation \( R \) as seen by transaction \( T \) at time \( \nu \).
(a) Historic Relation $R[T, \nu]$

$$R[T, \nu] = \begin{cases} 0 & \text{if } \nu < \text{Start}(T) \\ r[\nu] & \text{if } \text{Start}(T) = \nu \\ \nu(R[T, \nu - 1]) & \text{if } \exists u \in T : \nu(u) = \nu - 1 \land n \text{ updates } R \land \text{End}(T) \neq \nu - 1 \\ C[T, \nu](R[T, \nu - 1]) & \text{if } \text{End}(T) = \nu - 1 \\ R[T, \nu - 1] & \text{else} \end{cases}$$

(b) $R[\nu]$: Committed Tuple Versions at $\nu$

$$R[\nu](t) = \sum_{T \in H \land \text{End}(T) < \nu}^{n(R[T, \nu](t))} \sum_{i=0}^{n} R[T, \nu](t)[i] \times \text{validAt}(T, t, R[T, \nu](t)[i], \nu)$$

(c) Valid Tuple Versions from Transaction $T$ at $\nu$

$$\text{validAt}(T, t, k, \nu) = \begin{cases} 1 & \text{if } k = C_{T, \nu}^{d}(k') \land (\neg \exists T' \neq T : \text{End}(T') \leq \nu \land \text{updated}(T', t, k)) \\ 0 & \text{else} \end{cases}$$

(d) Tuple Versions Updated By Transaction $T$

$$\text{updated}(T, t, k) \iff \exists u \in T, t', i, j : R[T, \nu(u)](t)[i] = k \land R[T, \nu(u) + 1](t')[j] = U/D_{T, \nu(u) + 1}(k)$$

Fig. 5: Historic database definition

In contrast to the standard implementations of SI, we do not need to store additional start and end timestamps for tuple versions, because this information is already encoded in the annotation of a tuple. Intuitively, the time $\nu$ recorded in a version annotation corresponds to the start time of a tuple version. Under standard SI, a system attribute recording the end time of a tuple version needs to be updated when a new version of this tuple is created. Our version annotations do not explicitly store when a tuple version was invalidated by an update. Invalidation is implicitly encoded in the nesting of version annotations. Thus, tuple versions are immutable in our model in the sense that a part of an annotation wrapped in a version annotation may be used as part of a new more complex expression, but will not be modified itself. This greatly simplifies the reenactment approach presented in the next section, because we only need to deal with immutable data.

**Definition 5.9** Let $H$ be a history over a database $D$, $T$ the set of transactions in $H$, and $\forall$ a domain of version identifiers. The historic database $D_H$ based on $H$ is a set of historic relations. An $n$-ary historic relation $R^\nu$ is a function $D^n \times T \times \forall \rightarrow K^\nu$. We use $R[T, \nu]$ to denote the restriction of $R^\nu$ generated by fixing parameters $T$ and $\forall$ and $\nu$ and apply the same notation also for databases. Furthermore, we define $R[\nu]$, the snapshot of relation $R$ visible at $\nu$. The definitions of $R[T, \nu]$ and $R[\nu]$ are shown in Figure 5a.

The complexity of the above definition stems from the fact that it needs to account for the visibility rules of SI. Recall that a transaction $T$ under SI sees 1) its own updates and 2) the updates of transactions that have committed before $\text{Start}(T)$. The first condition is encoded in the recursive definition of $R[T, \nu]$ and the second one in the definition of $R[\nu]$.

**Relation Versions Visible Inside a Transaction.** $R[T, \nu]$ contains the result of applying the latest update of $T$ before $\nu$ to the version valid before the update. As a convention, we define $R[T, \nu] = \emptyset$ if $\nu < \text{Start}(T)$. The first update in a transaction sees $R[\text{Start}(T)]$, i.e., the version of $R$ containing all committed changes of transactions committed before $T$ started (2nd case in Figure 5b). We explain how to compute $R[\nu]$ below. Consider a transaction $T = u_1, \ldots, u_n, c$ and assume for simplicity that every update is modifying the same relation $R$. The second update $u_2$ within the transaction will see the version of $R$ produced by applying update $u_1$ to $R[\text{Start}(T)]$, the third update $u_3$ will run over the version of $R$ that is the result of applying update $u_2$ to the result of $u_1$ and so on. This is encoded by the 3rd and 5th case in Figure 5a. If $T$ executed an update on $R$ at version $\nu - 1$ then $R[T, \nu]$ is the result of applying the update to $R[T, \nu - 1]$. If transaction $T$ committed at $\nu - 1$ then we apply a commit operation to $R[T, \nu - 1]$ (4th case). If the transaction did not execute any operation at $\nu - 1$ then $R[T, \nu]$ is the same as $R[T, \nu - 1]$ (5th case). Note that this also includes the case where $\nu > \text{End}(T) + 1$.

**Relation Versions Containing Committed Changes.** Under SI, a transaction starting at $\nu$ will see a version of relation $R$ that contains all changes of transactions committed before $\nu$. Recall that we use $R[\nu]$ to denote this version of $R$. Figure 5b to 5d show the definition of $R[\nu]$. $R[\nu]$ can be expressed as a union (sum) over all tuple versions (annotations) created by committed past transactions as long as we make sure that we are not including the same tuple version more than
once. Furthermore, we should not include annotations that correspond to tuple versions which have been replaced with newer versions or were deleted. We enforce these two conditions using a predicate \texttt{VALIDAT}.

**Determining Valid Tuple Versions.** \texttt{VALIDAT}(T, t, k, ν) evaluates to 1 if two conditions are met: 1) annotation \( k \) was produced by transaction \( T \) which is the case if the outermost version annotation in \( k \) is from \( T \); 2) the tuple version corresponding to \( k \) was not updated (predicate \texttt{UPDATED}(T', t, k)) by another transaction \( T' \) that committed before \( ν \) (\( \text{End}(T') < ν \)).

**Checking for Tuple Updates.** \texttt{UPDATED}(T, t, k) is true if transaction \( T \) has overwritten the tuple version corresponding to \( t \) annotated with \( k \). That is, \( T \) has updated or deleted this tuple version. A transaction \( T \) has overwritten a summand \( k \) in an annotation of a tuple \( t \) if there exists an operation \( u \) (update or delete) within the transaction that has updated tuple \( t \) into tuple \( t' \). Recall that \( U/D \) stands for an update, or delete version annotation. Thus, there has to exist \( i \) and \( j \) so that a summand \( R(T, ν(u))[t][i] = k \) is in the annotation on \( t \) before the update and after the update the annotation on tuple \( t' \) contains a summand \( R(T, ν(u) + 1)[t'][j] \) is \( U_{T,ν(u)+1}(k) \) or \( D_{T,ν(u)+1}(k) \).

**Example 5.5** Consider the historic database states of Transaction \( T_4 \) from our running example.

\textbf{Relation \textit{Order} at Version 9:} Consider the version \texttt{Order\{T4, 9\}} valid before \( T_4 \) started. Since \texttt{Start(T1, 9)} = 9, this version is equal to \texttt{Order\{9\}}. We construct \texttt{Order\{9\}} by combining tuple annotations created by transactions that committed before \( T_4 \) started (Transactions \( T_1 \) and \( T_2 \) in the example) as long as these tuple versions have not been overwritten by another already committed transaction. For instance, consider tuple versions \( α_1 \) and \( α'_1 \) which were created by \( T_1 \) and \( T_2 \). The annotation for \( α'_1 = (oid1, Peter, 250) \) in \texttt{Order\{9\}} is computed by summing up all annotations on this tuple in the versions of relation \texttt{Order} created by \( T_1 \) and \( T_2 \). These are 0 for \( T_1 \) and \( k = C_{T_2,8}'(U_{T_2,7}(C_{T_1,6}(I_{T_1,2}(x_1)))) \) for \( T_2 \). The latter will be included in the annotation for \( α'_1 \) if we can determine that it was not invalidated by another transaction that committed after \( T_2 \) and updated \( α'_1 \). This is checked by computing predicate \texttt{VALIDAT}(T, t, \( α'_1 \), k, 9) which returns 1 if there does not exist any such transaction. Since there is no such transaction in the example, we get \texttt{Order\{9\}}(α'_1) = \( C_{T_2,8}'(U_{T_2,7}(C_{T_1,6}(I_{T_1,2}(x_1)))) \). Tuple \( α_1 = (oid1, Peter, 300) \) is annotated with \( k' = C_{T_1,6}(I_{T_1,2}(x_1)) \) in \( T_1 \) and 0 in \( T_2 \). Since Transaction \( T_2 \) updated \( α_1 \) and committed after \( T_1 \) and before version 9, the predicate \texttt{VALIDAT}(T, \( α_1 \), \( k' \), 9) evaluates to 0 and we get \texttt{Order\{9\}}(\( α_1 \)) = 0.

Importantly, lifted homomorphisms also commute with transactional histories.

**Theorem 5.5** Let \( h' \) be a lifted homomorphism (Theorem 5.3), \( h' \) commutes with histories.

5.5 Provenance Filtering

The annotation of a tuple stores its derivation history since the origin of the database. This amount of information can be overwhelming to a user. We now define how to restrict the provenance to tuples versions related to one transaction. In the \( \mathcal{K}' \) model this can be achieved by filtering parts of the annotations (to only track the effect of a certain set of statements) and by replacing subexpressions in annotations that represent parts of the history the user is not interested in with by evaluating them using the homomorphism \( h_U \) of the \( \texttt{UNV} \) operator. Furthermore, for \( \mathbb{N}[X]' \)-relations we replace the resulting polynomial with a fresh variable disambiguated by the tuple’s identifier. For example, if a subexpression \( C_{T',\nu'}^\mathit{id}'(I_{T',\nu'}(x_1) \times I_{T',\nu'}(x_2))) \) where \( T' \) is a transaction different from the transaction \( T \) we are interested in occurs in an annotation we would replace it with \( C_{T',\nu'}^\mathit{id}(x_{id}) \). Reconsider Example 2.2 as an example for the application of the definition below.

**Definition 5.10** Let \( T \) be a transaction in a history \( H \) over database \( D \). The provenance \( D[T] \) restricted to \( T \) is derived from \( D[T, \text{End}(T)] \) by replacing each relation \( R[T, \text{End}(T)] \) with \( R[T] \) as defined below.

\[
R[T](t) = \sum_{i=0}^{α(R[T, \text{End}(T)])(t)} \text{filt}(R[T, \text{End}(T)])(t)[i]
\]

\[
\text{filt}(k) = \begin{cases} 
C_{T,\nu}^{\mathit{id}}(h_f(k')) & \text{if } k = C_{T,\nu}^{\mathit{id}}(k') \\
0 & \text{else}
\end{cases}
\]

\[
h_f(k) = \begin{cases} 
\text{if } k \in K \\
U/I/D_{T,\nu}^\mathit{id}(h_f(k')) & \text{if } k = U/I/D_{T,\nu}^\mathit{id}(k') \\
h_f(k_1) + h_f(k_2) & \text{if } k = k_1 + k_2 \\
h_f(k_1) \times h_f(k_2) & \text{if } k = k_1 \times k_2 \\
C_{T,\nu}^{\mathit{id}}(h_U(k')) & \text{if } k = C_{T,\nu}^{\mathit{id}}(k') \land K \neq \mathbb{N}[X] \\
C_{T,\nu}^{\mathit{id}}(x_{id}) & \text{if } k = C_{T,\nu}^{\mathit{id}}(k') \land K = \mathbb{N}[X]
\end{cases}
\]

6 Reenactment Queries

We now introduce reenactment which enables us to reconstruct the provenance of an update \( u \) or transaction \( T \) by executing a reenactment query \( \mathbb{R}(u) \) respectively \( \mathbb{R}(T) \). Such a query is annotation equivalent to \( u \) respectively \( T (u \equiv_{\mathbb{N}[X]' \mathbb{R}(u)} u) \), i.e., the operation and its
reenactment query produce the same result and prove-
nance. As we will demonstrate later this also implies
equivalence for any other MV-semiring $K'$. We intro-
duce a new operator that adds version annotations, be-
cause this is required for reenactment since the op-
erators of $RA^+$ do not introduce new version annota-
tions.

**Definition 6.1** The operator $\alpha_{X,T,\nu}(R)$ for $X \in \{I, U, D, C\}$ takes as input a $K'$-relation $R$ and returns a $K'$-relation where each sammand in an annotation $k$ is wrapped in $X_{T,\nu}^{(k)}$. Here $id(k)$ denotes the identifier of the outermost version annotation in annotation $k$.

$$\alpha_{U/D,T,\nu}(R)(t) = \sum_{i=0}^{n(R(t))} U/D_{T,\nu}^{i}(R(t)[i])$$

$$\alpha_{I,T,\nu}(R)(t) = \sum_{i=0}^{n(R(t))} I_{T,\nu}^{id_{new}}(R(t)[i])$$

$$\alpha_{C,T,\nu}(R)(t) = \sum_{i=0}^{n(R(t))} \text{COM}[T,\nu](R(t)[i])$$

Note that $id_{new}$ is determined using skolem function $f_{id}$ as described in Section 5.2 and that $\alpha_{C,T,\nu}$ uses $\text{COM}[T,\nu]$ introduced Definition 5.7.

### 6.1 Update Reenactment

We first define reenactment for an update operation $u$ that is executed over the historic database seen by $u$’s transaction $T$ at the time of the update ($R(T,\nu(u))$). Note that here we abuse notation and treat $R(T,\nu)$ as a syntactic construct that we can substitute with an algebraic expression which computes this version of $R$. For example, $Q(D[T,\nu])$ denotes the query $Q$ where every access to a relation $R$ is substituted by $R[T,\nu]$.

**Definition 6.2** Let $H$ be a history over database $D$. The reenactment query $\mathbb{R}(u)$ for operation $u$ in $H$ is:

$$\mathbb{R}(U/\theta,A,T,\nu|R) = \alpha_{U,T,\nu}|_{U}(\Pi_{A}(\sigma_{\theta}(R[T,\nu])))$$

$$\text{COM}[T,\nu](R(t)) = \alpha_{T,\nu}^{i}(\sigma_{\theta}(R[T,\nu])) \cup \sigma_{\theta}(R[T,\nu])$$

An update modifies a relation by applying the expressions from $A$ to all tuples matching condition $\theta$. All other tuples are not modified. We can compute the result of an update as the union between these sets. An insert statement adds the result of a query to the affected relation. It can be reenacted as the union between the relation and the insertion query result. A deletion wraps tuples matching its condition in deletion annotations. Thus, it can be expressed as the union between the original tuples that do not match the condition and the deleted versions of tuples matching the condition.

**Example 6.1** Consider the reenactment query $\mathbb{R}(u_1)$ for the update $u_2 = U[d=1,p \rightarrow 250; T_2,6](\text{Order})$ of example Transaction $T_2$. We abbreviate relation $\text{Order}$ as $O$ and attributes like in previous examples.

$$\mathbb{R}(u_1) = \mathbb{R}(u_2) = \mathbb{R}(u_3)$$

**Theorem 6.1** Let $u$ be an update and $\mathbb{R}(u)$ its reenactment query. Then, $u \equiv_{\mathbb{R}(u)} \mathbb{R}(u)$.

Based on this theorem, reenactment queries can simulate the effect of any update expressible in our model.

### 6.2 Transaction Reenactment

To reenact a transaction, we merge the reenactment queries for the updates of the transaction in a way that respects the visibility rules enforced by the SI protocol. Under SI, each update $u_i$ of a transaction $T$ sees the version of the database at transaction start plus local modifications of updates $u_j$ from $T$ with $j < i$. Thus, effectively, each update $u_i$ updating a table $R$ is evaluated over the annotated relation produced by the most recent update $u_j$ with $j < i$ that updated $R$. Since we have proven that $u \equiv_{\mathbb{R}(u)} \mathbb{R}(u)$, each reference to a relation $R(T,\nu)$ produced by update $u_j$ can be replaced with $\mathbb{R}(u_j)$ (as mentioned above we treat $R(T,\nu)$ as a symbolic expression in this context). Applying this substitution recursively and adding an annotation operator to wrap the final outputs in commit annotations results in a single query $\mathbb{R}(T)$ per relation $R$ affected by $T$. Technically, the reenactment of a transaction $T$ is a set of queries. However, abusing terminology we refer to this set as the reenactment query of $T$ and by $T \equiv_{\mathbb{R}(u)} \mathbb{R}(T)$ denote that each reenactment query for a relation $R$ is equivalent to the effect that transaction $T$ has on this relation.

**Definition 6.3** Let $T = u_1,...,u_n,c$ be a transaction in a history $H$. We use $\mathbb{R}(T)$ to denote all relations targeted by at least one update of $T$ and last update executed before $\nu$ in $T$ that updated table $R$. The reenactment query $\mathbb{R}(T)$ for $T$ is:

$$\mathbb{R}(T) = \{R[T,R] | R \in \mathbb{R}(T)\}$$

$$\mathbb{R}(T) = \mathbb{R}(T) \cup \mathbb{R}(\text{last}(T,R,\text{End}(T)))$$

where query $\mathbb{R}(u)$ is computed as follows. We initialize $\mathbb{R}(u) = \mathbb{R}(u)$ and then apply the following substitution rule until a fix point is reached (only relation mentions of the form $S[\text{Start}(T)]$ remain):
– Pick a relation mention $S[T, ν]$ in the current version of $R^K(u)$
– If $∃u' ∈ T : u'$ updates $S ∧ ν(u') < ν$ then replace $S[T, ν]$ with $R^K(\text{Last}(T, R, ν))$
– Else replace $S[T, ν]$ with $S[\text{Start}(T)]$

Example 6.2 Consider the transaction $T_3$ from the running example. Let us refer to its operations as $u_1$ and $u_2$. We abbreviate relation names as $O$ (Order), $S$ (Outstanding), and $C$ (Collection) and attribute names as in previous examples with the exception that attribute date is denoted as $e$. Consider the reenactment query for $T_3$ on $C$. The last update modifying $C$ is $u_2$. Thus,

$$R^C(T_3) = α_{C,T,13}(R^C(u_2))$$

Operation $u_2$ is an insert into relation $\text{Collection}$ using a query over the state of relation $\text{Outstanding}$ valid at version 10. The reenactment query for this update is:

$$R^C(u_2) = α_{I,T_2,11}(Π_{o,a}(σ_{t<2000-06}(S[T_3, 10])))$$

$$∪ C[T_3, 10]$$

The last update of Transaction $T_3$ that modified relation $\text{Outstanding}$ before version 10 is $u_1$. Thus, the access to $S[T_3, 10]$ in $R^C(u_2)$ is replaced with $R^K(u_1)$. Relation $\text{Collection}$ has not been modified by any other update of $T_3$. Thus, $C[T_3, 10]$ is replaced with $C[\text{Start}(T_3)]$.

$$R^C(u_2) = α_{I,T_2,11}(Π_{o,a}(σ_{t<2000-06}(R^K(u_1)))) ∪ C[8]$$

The access to relation $\text{Outstanding}$ by update $u_1$ is not replaced in $R^K(u_1)$, because there is no update operation in transaction $T_2$ that updated this relation before $u_1$ was executed. The final reenactment query $R^C(T_3)$ is:

$$R^C(T_3) = α_{C,T,13}(R^C(u_2))$$

$$∪ C[T_3, 10]$$

$$∁[8]$$

We now prove that the reenactment query for a transaction is equivalent to this transaction.

Theorem 6.2 Let $T$ be a transaction and $\text{R}(T)$ its reenactment query. Then: $T \equiv_{\mathbb{N}[X]} R(T)$.

Green demonstrated [10] that $Q \subseteq_{\mathbb{N}[X]} Q' \Rightarrow Q \subseteq_{K} Q'$ if $K$ is naturally ordered and, thus $Q \equiv_{\mathbb{N}[X]} Q' \Rightarrow Q \equiv_{\mathbb{N}} Q'$. The result is based on the existence of surjective semiring homomorphisms. We do not define what it means for a semiring to be naturally ordered here, but note that many important semirings including all semirings considered here are naturally ordered. Based on the theorem shown below this result translates to queries using the annotation operation defined above and updates in MV-semirings. Thus, reenactment queries also produce the same updated relation as the original operation under bag semantics.

Theorem 6.3 For $Q$ and $Q'$ be two $\mathcal{RA}^+$ queries and $K$ a naturally ordered semiring. Then $Q \equiv_{\mathbb{N}} Q' \Rightarrow Q \equiv_{K} Q'$. Let $Q$ and $Q'$ be two updates or $\mathcal{RA}^+$ queries that may use the annotation operator $α$ and $K$ a naturally ordered semiring, then $Q \equiv_{\mathbb{N}[X]} Q' \Rightarrow Q \equiv_{\mathbb{N}} Q'$.

The theorem above implies that reenactment can be used to replay transactions over any $\mathcal{K}$-database not just a $\mathbb{N}[X]$-database. Furthermore, using Unv we can use reenactment compute the same $\mathcal{K}$-database as would have been produced by applying Unv to the result of the reenacted transaction.

7 Relational Reenactment using Time Travel and Audit Logging

We now introduce techniques for retrieving the provenance of transactions using standard DBMS based on a relational encoding of reenactment queries. Our approach uses an audit log to determine which SQL statements were executed when and by which transaction. We demonstrate how reenactment queries can be translated into standard relational algebra queries with time travel that produce a relational encoding of provenance restricted to a transaction (as explained in Section 5.5).

7.1 Relational Encoding of $\mathcal{K}$-Relations

We extend the relational encoding of provenance polynomials introduced for the Perm [17] project with additional columns that encode version annotations. To encode the filtered provenance $R[T]$ of a transaction $T$ we: 1) normalize $\mathcal{K}$-expressions according to the operations that were applied to the data and 2) use additional attributes to represent a normalized $\mathbb{N}[X]$-polynomial.

Normal Form. The basic idea behind this encoding is to represent variables in a normalized polynomial by actual tuple values from the inputs of the query. In particular, we take a polynomial in the normal form introduced in Definition 5.3 that is a sum of products (and version annotations) and order the variables and version annotations in each summand according to the relation and update they belong to. Given the algebra tree for a reenactment query, variables in products mixed with version annotations are ordered according to the leaves of the algebra tree. We add additional attributes to be able to encode such a product and its version annotations, and represent each summand in a normalized polynomial as a separate tuple.
\[ \text{Scn}(\text{Rel}(R[T])) = \text{Scn}(R) \triangleright \text{IDP}(\text{Scn}^{\text{Add}}(T))(T, R) \triangleright \text{UC} \]

\[ \text{Scn}^{\text{R}}(T, R) = \begin{cases} \{ \mathcal{P}(T, \text{Last}(R, T, v)) \} & \text{if } \forall u \in T : u \text{ updates } R \land v(u) < v \\
\{ \mathcal{P}(R) \} & \text{else} \end{cases} \]

\[ \mathcal{P}(T, t \rightarrow k) = \text{const} \]

\[ \mathcal{T}(T) = \begin{cases} \{ \text{Scn}^{\text{c}}(T, R) \triangleright \text{Scn}^{\text{r}}(T, X_1) \triangleright \ldots \triangleright \text{Scn}^{\text{r}}(T, X_n) \triangleright \text{UC}_\text{post} \} & \text{if } u = \mathcal{T}(Q(X_1, \ldots, X_n), T, v)(R) \text{ where either } X_i = R_i \text{ or } X_i = (t \rightarrow k_i) \\
\{ \text{Scn}^{\text{c}}(T, R) \triangleright \text{UC}_\text{post} \} & \text{else} \end{cases} \]

\[ \text{Rel}(R[T]) = \bigcup_{i \in R} \bigcup_{x = 0}^{|R[T]|} t \triangleright \text{Rel}^{\text{Add}}(T, R, R[T][i])[i] \triangleright \text{True} \]

\[ \text{EncR}(R, k) = \begin{cases} \{ T, v', id, t(x) \} & \text{if } k = C^{\text{Add}}_{T, v}(x) \\
\text{NULL}(\mathcal{P}(R)) & \text{else} \end{cases} \]

\[ \text{EncR}(t \rightarrow k, j) = \begin{cases} \text{id} & \text{if } k = s_{i,d} \\
\text{null} & \text{else} \end{cases} \]

\[ \text{EncU}(T, u, k) = \begin{cases} \text{Rel}^{\text{c}}(T, R, k) \triangleright \text{True} & \text{if } u \text{ is a delete or update} \\
\text{Rel}^{\text{c}}(T, R, k) \triangleright \text{False} & \text{if } u \text{ is an insert} \land k = A_{\text{post}(u)}(k') \\
\text{NULL}(\text{Scn}^{\text{r}}(T, R)) \triangleright \text{Rel}^{\text{c}}(T, X_1, k_1) \triangleright \ldots \triangleright \text{Rel}^{\text{c}}(T, X_n, k_m) \triangleright \text{True} & \text{if } u \text{ is a delete or update} \land k \neq A_{\text{post}(u)}(k') \\
\text{NULL}(\text{Scn}^{\text{r}}(T, R)) \triangleright \text{NULL}(Q) \triangleright \text{False} & \text{if } u \text{ is an insert} \land k = A_{\text{post}(u)}(k_1 \times \ldots \times k_m) \\
\text{NULL}(\text{Scn}^{\text{r}}(T, R)) \triangleright \text{NULL}(Q) \triangleright \text{False} & \text{if } u \text{ is an insert with query } Q \land k \neq A_{\text{post}(u)}(k_1 \times \ldots \times k_m) \end{cases} \]

**Fig. 6:** Schema and instance of the relational encoding of \( R[T] \)

**Definition 7.1** Let \( T \) be a transaction. An \( \mathbb{N}[X]^v \) annotation in \( R[T](t) \) is in ordered normal form if it is normalized according to **Definition 5.4** and variables in each summand \( k_i \) are sorted according to \( \mathbb{R}^R(T) \).

**Schema.** We first define the schema of a relational encoding \( \text{Rel}(R[T]) \) of the provenance for a transaction \( T \) using a renaming function \( P \) that maps a relation and attribute name to a provenance attribute name. In the following we use \( \text{Scn}(R) \) to denote the schema of a relation \( R \) and \( P(R) \) to denote the list of attribute names containing \( P(R, A) \) for each \( A \in \text{Scn}(R) \) and \( \mathcal{P}(R) \) to denote \( P(R) \) plus three additional attributes \( Id, XId \) and \( V \) that encode a tuples identifier, the transaction creating the tuple version, and the time at which the update creating the tuple version was created, respectively. Furthermore, let \( \text{IDP} \) denote a function that takes a list of attribute names and adds unique identifiers to names that occur more than once in the list. We use \( \triangleright \) to denote list concatenation, e.g., concatenating lists of attributes.

**Definition 7.2** Let \( T \) be a transaction, \( U_i \) denote a boolean attribute representing the version annotation of update \( u_i \in T \), and \( U_C \) denote a boolean attribute representing the commit annotation of \( T \). The name of attribute \( U_i \) encodes \( v(u_i) \), the type of update \( u_i \) (insert, delete, update), and the query \( Q \) in case the update is an insert. We use \( \text{pos}(u) \) to denote the position of update \( u \) in transaction \( T \). The schema of the relational encoding \( \text{Rel}(R[T]) \) is defined in **Figure 6**.

The schema is constructed recursively by tracing back from the last operation in the transaction that modified relation \( R \). If this operation \( u \) is an update or delete then we add an attribute \( U \) for storing whether a version annotation for \( u \) is used in an annotation. For updates or deletes that are the first operation modifying a relation \( R \), the schema will contain provenance attributes to store the tuple corresponding to a variable in an annotation. For instance, if a transaction \( T \) consists of two updates \( u_1 \) and \( u_2 \) which both updated relation \( R \), then each annotation on a tuple in \( R \) will be of the form \( U^d_{Id}(u_2)(U^d_{Id}(u_1)(x)) \) where both version annotations are optional. Consequently, the schema of the relational encoding for such annotations will have two attributes \( U_1 \) and \( U_2 \) to denote which version annotation is present and provenance attributes for relation \( R \) to store the tuple corresponding to variable \( x \) in the annotation. Since insert operations insert the result of a query into a relation, we have to add provenance attributes to represent the provenance of input tuples to such a query. Assume that the query of an insert is defined over \( X_1 \times X_M \) where each \( X_i \) is either an access to a relation \( R_i \) or a singleton operator \( \{ t \rightarrow x \} \). To be able to store the annotation of a tuple from relation \( R_i \) in the query’s provenance, we have to add attributes to represent all previous updates of \( T \) on \( R_i \). Such a list of attributes is then constructed in the same fashion as for the last update of the transaction using \( \text{Scn}^{r}(T, R_i) \). In case of a singleton operator \( \{ t \rightarrow x \} \) we have to add an attribute to store the variable assigned to the tuple \( t \). Note that even though the definitions of \( \mathcal{P}(T, u) \) and \( \text{Scn}^{r}(T, R) \) are mutually recursive, these definitions are not circular because \( \text{Scn}^{r}(T, R) \) only refers to \( \mathcal{P}(T, u) \) for updates \( u \) with \( v(u) < v' \). Thus, \( \text{Scn}^{r}(T, R) \) may only depend on \( \text{Scn}^{r}(T, R) \) if \( v' < v \).

**Instance.** The instance \( \text{Rel}(R[T]) \) of the relational encoding of \( R[T] \) is created by representing each summand \( k_i \) in a normalized annotation \( R[T](t) = \sum^\text{const}_k k_m \) as a separate tuple. The construction of the schema guarantees that this will always be possible.
Definition 7.3 Consider the provenance $\mathcal{R}[T]$ of transaction $T$ in ordered normal form and let $\text{Null}(P(R))$ and $\text{Null}(Q)$ denote a list of null values with the same arity as $P(R)$ and the provenance schema for $Q$ (the list of $\text{Rel}^{\sigma(u)}(R, X, j, k_j)$ attributes), respectively. Let $t(x)$ denote the tuple corresponding to a variable $x$. The relational encoding $\text{Rel}(\mathcal{R}[T])$ is defined in Figure 4.

The relational encoding of a normalized $\mathcal{N}[$X$]^{\nu}$-annotation of a tuple in $\mathcal{R}[T]$ is constructed following the same procedure as for its schema. For each summand $k$ in an ordered normalized annotation of a tuple $t$ in $\mathcal{R}[T]$ we create a tuple in $\text{Rel}(\mathcal{R}[T])$ by concatenating $t$ and the relational encoding of $k$. The encoding of $k$ is constructed iteratively by encoding and stripping of parts of $k$ corresponding to updates in $T$.

Example 7.1 Figure 3 shows a simplified version of $\text{Rel}(\mathcal{C}[T_3])$ for example Transaction $T_3$. We abbreviate $\mathcal{C}$ and $\mathcal{S}$ as $C$ and $\mathcal{S}$, and attribute names as in previous examples. Note that we have omitted the $\mathcal{U}_C$, $\mathcal{X}$, $\mathcal{V}$, $\mathcal{I}$, and $P(C)$ attributes to simplify the representation. MV-annotations are shown to the left of each tuple. We use $u_1$ and $u_2$ to denote the two operations of this transaction. The schema of this encoding is constructed as follows:

\[
\begin{align*}
\text{Sch}(\text{Rel}(C[T_3])) &= \text{Sch}(C) \triangleright ID_T(\text{Sch}(T_3, C)) \triangleright \text{U}_C \\
\text{Sch}(T_3, C) &= \mathcal{P}(T_3, u_2) = \text{Sch}(T_3, C) \triangleright \mathcal{P}(T_3, S) \triangleright U_1 \\
\text{Sch}(T_3, S) &= \mathcal{P}(T_3, u_1) = \text{Sch}(T_3, S) \triangleright U_2 \\
\text{Sch}(T_3, S) &= \mathcal{P}(S) = \text{Id}, \mathcal{X}, \mathcal{V}, \mathcal{P}(S, o), \mathcal{P}(S, a), \mathcal{P}(S, d)
\end{align*}
\]

In this schema, attributes $U_1$ and $U_2$ represent the version annotations for updates $u_1$ and $u_2$. The insert $u_2$ in $T_3$ uses a query $\mathcal{P}_T(\mathcal{S} \ni (\mathcal{X}, \mathcal{V}, \mathcal{I}, \mathcal{O}, \mathcal{A}, \mathcal{D}) \mathcal{S}^{(2000 - 06)}(\mathcal{O}) \mathcal{S}^{(2000 - 06)}(\mathcal{O}))$. Thus, the schema contains provenance attributes for relation $\mathcal{S}^{(2000 - 06)}(\mathcal{O})$. Attribute $U_1$ is added, because update $u_1$ has previously updated this relation. Consider the first tuple in Figure 3, which represents the single summand in the annotation of tuple $(\mathcal{X}, \mathcal{V}, \mathcal{I}, \mathcal{O}, \mathcal{A}, \mathcal{D})$. The tuple was derived by updating the tuple annotated with $x_3$ in relation $\mathcal{S}^{(2000 - 06)}$ and then inserting a new tuple into relation $\mathcal{S}^{(2000 - 06)}$ based on this tuple. Both version annotation attributes are set to true (both updates were involved in the derivation) and the provenance attributes for relation $\mathcal{S}^{(2000 - 06)}$ are used to store the tuple annotated with $x_3$ in the input.

Given this relational encoding we need to prove that it is lossless, i.e., the encoded MV-relation $\mathcal{R}[T]$ can be recovered from $\text{Rel}(\mathcal{R}[T])$.

Theorem 7.1 The $\text{Rel}(\mathcal{R}[T])$ operation is lossless.

7.2 Audit Log and Time Travel

We require the DBMS we use for provenance computation to keep an audit log that stores the SQL code for each update plus 1) when the update was executed and 2) the identifier (XID) of its transaction. The audit log is used to determine the operations of a transaction and the database version they have accessed. We assume a standard SI based implementation of time travel as supported in similar fashion by multiple DBMS. Each tuple is annotated with a system time interval (transaction time) that encodes when this tuple version is valid in the database. Update operations create new tuple versions and invalidate tuple versions that are updated by setting their end time to the current time. These modifications are only visible in the updating transaction. When a transaction commits, then new tuple versions are created for all modified tuples with start time set to the transaction commit time. A snapshot $\mathcal{R}_t$ of relation $\mathcal{R}$ contains all committed tuple versions valid at $\nu$. Snapshots have additional attributes $\mathcal{Y}_t$ and $\mathcal{T}_t$ storing validity time intervals as well as $\mathcal{X}_t$ and $\mathcal{I}_t$ storing the transaction and tuple identifiers, respectively.

7.3 Relational Implementation of Reenactment

We now discuss how $\mathcal{K}^{\nu}$-relational reenactment queries can be rewritten as standard relational (bag semantics) queries which produce $\text{Rel}(\mathcal{R}[T])$ for a transaction $T$. This rewriting of $\mathcal{K}^{\nu}$-queries into bag semantics queries (expressible in SQL) extends previous results for rewriting $\mathcal{K}$-relational queries into bag semantics [17, 15]. A query is rewritten by recursively applying rewrite rules for single operators in a top-down fashion. We apply a selection on the boolean version annotation attributes to only return tuple versions from $\mathcal{R}[T]$, i.e., that were affected by at least one update of transaction $T$.

Definition 7.4 Let $T = t_1, \ldots, t_n, c$ be a transaction and let $\mathcal{U}_t$ denote the version annotation created by the $i$th update in $T$. The relational translation $\mathcal{TR}(\mathcal{R}(T))$ of the reenactment query $\mathcal{R}_\mathcal{R}(T)$ restricted to $\mathcal{R}[T]$ is computed from $\mathcal{R}(T)$ as shown below. The rewrite operator $\mathcal{R} \mathcal{E} \mathcal{W}$ is defined in Figure 4. $\mathcal{R}(\mathcal{P}(q))$ denotes a singleton relation with null values for all provenance attributes of $q$ except for version annotation attributes which are set to false. Furthermore, $\mathcal{I} \mathcal{D}_x$ is a function that adds a suffix ‘$\mathcal{I}_x$’ to attribute names in a list.

\[
\mathcal{TR}(\mathcal{R}(T)) = \mathcal{S}_{\mathcal{U}_1, \mathcal{V}_1, \ldots, \mathcal{U}_n} \mathcal{R}(\mathcal{P}(q))
\]

The query produced by the rewrite rules of Figure 4 returns the relational encoding of provenance introduced previously. There are two rules for the union
**Example 7.2** Consider the reenactment query for transaction $T_3$ (Example 6.4) and its standard relational algebra version shown in Figure 8. Accesses to relations Collection (C) and Outstanding (S) are replaced with snapshots and the attributes of these relations are duplicated to encode the variables in the annotations of tuples of C and S. Recall that we represent variables in annotations using the tuples they are annotating using the Xid, TTb, and V to encode the commit annotation of the past transaction creating the tuple. The part of the query corresponding to update $u_1$ ($R^S(u_1)$) has been rewritten by replacing $S[8]$ with its rewritten counterpart. The version annotation operator has been replaced with a projection adding true as the value for annotation attribute $U_t$. For attribute $U_t$, which is not in the right input (tuples that were not updated by $u_1$), we add $p_{U_t}(\{\{\text{false}\}\})$ (we use $p_{U_t}$ to denote renaming of the single attribute of $\{\{\text{false}\}\}$). Update $u_2$ is an insert that accesses relation Outstanding. Re-call that in $R(u_2)$ the access to this relation was replaced with $R(u_1)$. The rewritten version of $R^S(u_2)$ applies crossproducts with singletons for union compatibility and uses $I_{D_1}$ to append a suffix to every annotation attribute to prevent name clashes between the two inputs of the union. The annotation operator in $R(u_2)$ is replaced with a projection $\Pi_{\text{true}} \cup \Pi_{\text{false}}$. Finally, the selection $\sigma_{U_t \cup U_t}$ ensures that only tuples that are affected by at least one operation from $T_3$ are returned.

This translation of reenactment queries returns the encoding of $R[T]$ that as defined in Section 7.1.

**Theorem 7.2** Let $T$ be a transaction. Then:

$$TR(R(T)) = REL(R[T])$$
8 Implementation

We have implemented provenance computation for transactions in GProM (Generic Provenance Middleware), a provenance middleware for standard DBMS. Figure shows an overview of the system. GProM translates SQL statements with provenance requests into relational algebra. Requests for transaction provenance are processed by the reenactor that constructs a reenactment query using the audit log of the backend DBMS. The provenance rewriter rewrites this reenactment query to compute its provenance. Afterwards, we optimize the algebra expression using heuristic rules. The simplified expression is then compiled into SQL code. For an overview of GProM and its unique features see [3].

8.1 Reenacting With CASE

One disadvantage of the reenactment queries produced by our approach is that each update is translated into a union between two accesses to the input relation. For a sequence of updates in a transaction this leads to queries where the left and right input of each such union is again a union operation. Unless intermediate results are reused, this leads to an exponential number of union operations (in the number of updates). Instead of computing the union between the set of updated tuples and non-updated tuples, we can use the SQL CASE construct to decide for each tuple whether it should be updated or not. We can reenact update \( U[\theta, A, T, \nu](R) \) using a projection (\( \text{SELECT} \)) constructed as follows. For each expression \( e \rightarrow a \) in \( A \) we add \( \text{CASE WHEN } \theta \text{ THEN } e \text{ ELSE } a \text{ END AS } a \) to the projection. The values of version attributes can be computed in a similar fashion. This approach is also applicable for deletes.

8.2 Prefiltering Provenance

The relational encoding of reenactment introduced in Section filters out tuples that were not affected by any update by applying a selection on \( U_1 \backslash \ldots \backslash U_n \) to the result of reenactment. Thus, the reenactment query is evaluated over all tuples from \( R_{\text{Start}(T)} \). We now discuss two optimizations that filter out tuples early on.

Prefiltering With Update Conditions. The naive method can be improved if we can determine upfront which tuples will be affected by a transaction. Consider a transaction \( T = u_1, \ldots, u_n, c \) and a tuple \( t \) valid at transaction start. Tuple \( t \) was modified by a subset (potentially empty) of the updates of \( T \). If \( t \) is affected, then there has to exist a first update \( u_i \) in \( T \) that modified tuple \( t \). Thus, \( t \) has to fulfill the condition of \( u_i \). This observation can be used to characterize the set of tuples affected by the transaction. In particular, this is the set fulfilling the condition \( \theta_1 \lor \ldots \lor \theta_n \), where \( \theta_i \) is the condition of the \( i \)-th update operation. Hence, it is safe to apply a selection on this condition to the input of reenactment. This approach is not applicable to a relation \( R \) if one of the transaction’s inserts uses a query that accesses relation \( R \). Delete operations can be handled like update operations whereas inserts create new tuples and there is no need for prefiltering.

Join With Committed Tuple Versions. The version of the database at commit of transaction \( T \) will contain all tuple versions created by \( T \). Recall that that snapshots use a column \( Xid \) to store the updating transaction. Thus, we can determine which tuple versions got created by a transaction \( T \) by running a query \( \sigma_{\text{Xid}=\text{T}}(R_{\text{End}(T)}) \). To retrieve the versions of these tuples valid at transaction start, we can join the result of this query with \( R_{\text{Start}(T)} \). Recall that we assume that the database system uses unique immutable tuple identifiers stored in attribute \( Id \). We join on this identifier, i.e., in the reenactment query we replace \( R_{\text{Start}(T)} \) with \( \Pi_{\text{Xid}}[\sigma_{\text{Xid}=\text{T}}(R_{\text{End}(T)})] \). This approach is only applicable to relations that are not accessed by any insert’s query in the transaction.

9 Experiments

In our experiments we study 1) the performance of provenance computation and 2) the overhead for transaction execution comparing our approach (using reenactment, audit logging and history maintenance) against an approach that directly stores provenance. We use a synthetic workload to evaluate how our approach scales in various parameters and a TPC-C workload to test its performance for realistic transactions. All experiments were executed on a machine with 2 x AMD Opteron 4238 CPUs (12 cores in total), 128 GB RAM, and 4 x 1TB 7.2K HDs in a hardware RAID 5 configuration.

9.1 Setup and Workload

Datasets and Workload. We use a relation with five numeric columns. Values for these attributes are chosen from a uniform distribution. We created variants \( R10K, R100K, \) and \( R1000K \) with 10K, 100K, and 1M tuples and no significant history (\( H0 \)). Additionally, we generated three variants of \( R1000K \) with different history sizes \( H10, H100, \) and \( H1000 \) (100K, 1M, and 10M tuples history). At first, we only consider transactions that consist solely of update statements. We vary the following parameters: \( U \) is the number of updates per
transaction, e.g., $U10$ is a transaction with 10 updates. $T$ is the number tuples affected by each update. Unless stated otherwise, we use $T1$. The tuple to be updated is selected using the primary key. All transactions were executed under isolation level SERIALIZABLE ($SI$).

**Compared Methods.** We compare different configurations for computing provenance of a single transaction - each using a subset of the optimizations described in Section 8. Experiments were repeated 100 times and we report the average runtime. **NoOpt** (N): Computes the provenance of all tuples in a relation, even tuples that were not affected by the transaction, i.e., we do not apply the filter condition on the version annotation attributes. **Prefilter** (P): Only returns provenance of tuples affected by the transaction using a selection on the disjunctions of all conditions for the transaction’s updates (see Section 8.2). The database system was instructed to materialize the intermediate result corresponding to each update in the reenactment query using temporary relations. **Prefilter+Merge** (PM): This is the same as Prefilter, but we merge operators (particularly, projections) to reduce the number of query blocks.  

**HistJoin** (HJ): We use a join to compute partial provenance as described in Section 8.2. This configuration merges operators where possible.

### 9.2 Performance of Provenance Computation

In the first set of experiments we have executed the transactional workload beforehand and measure the performance of computing provenance for transactions from this workload to study how our reenactment approach scales in database size, size of the history, and complexity of the transaction (number of operations, amount of modified tuples, mix of update types).

**Relation Size and Updates/Transaction.** We compute the provenance of transactions varying the number of updates per transaction ($U1$, $U10$, $U100$, and $U1000$) and the size of the database ($R10K$, $R100K$, and $R1000K$). We use the relation without significant history ($H0$) and ran N and PM. Figure 10 shows the runtime of these provenance computations. We scale linearly in $R$ and $U$. By reducing the amount of data to be processed by the reenactment query and by merging operators, the PM approach is up to three orders of magnitude faster than the naive N configuration.

**History Size.** We have computed the provenance for transactions with 10 updates ($U10$) over relations with 1M tuples ($R1000K$) and history sizes: $H0$, $H10$, $H100$, and $H1000$. As shown in Figure 11, $N$ exhibits almost constant performance. The runtime is dominated by evaluating the reenactment query over 1M tuples (all tuples in one version of the relation) hiding the impact of scanning the history. Since we have not created any indexes on the history relations, the PM approach only has the advantage of processing less tuples in the provenance computation, but still has to scan most of the history to find tuples that were updated.

**Comparing Optimization Techniques.** Figure 12 shows results for varying the number of updates ($U1$, $U10$, $U100$, and $U1000$) using $R1000K$-$H1000$. Compared with P, PM benefits from avoiding materialization. This optimization is more effective for larger transactions, because reenactment queries for such transactions are increasingly complex. While resulting in ~20% improvement for U100, it improves the runtime by a factor of roughly 10 for U1000. The cost of PM is affected by the first selection that is applied to 1M tuples (no index on the history relation). This condition is linear in the number of update operations. The runtime
of $HJ$ is almost not affected by parameter $U$, because it is dominated by the join between historic relations. $PM$ outperforms $HJ$ by a factor of about 3.

**Affected Tuples Per Update.** Figure 13 shows results for $U10$ where each update modifies 10, 100, 1000, or 10000 tuples from relation $R1000K-H1000$. As evident from Figure 13, the runtime is not significantly affected when increasing the number of affected tuples per update. It is dominated by scanning the history and filtering out updated tuples ($PM$) or the self-join between historic relations ($HJ$). Increasing the $T$ parameter by 3 orders of magnitude results in an runtime increase of about 150% ($PM$) and 20% ($HJ$).

**Index vs. No Index.** We study the effect of replicating the indexes defined for a relation to its corresponding history relation. Figure 14 shows the results with and without indexes. We have used $R1000K-H1000$ and have varied $U$ from $U1$ to $U1000$. We omit the $N$ parameter, because more benefit from indexes and $P$ (consistently outperformed by $PM$) configurations. Using indexes improves execution time of queries that apply $PM$ considerably.

**Inserts and Deletes.** We now also use inserts and deletes in addition to updates. We have used the $R1000K$ relation in this experiment. Each operation is chosen randomly (25% probability) from: 1) An update as used in the previous experiments ($T1$); 2) an insert that inserts one new tuple; 3) an insert that inserts the result of a query over a different relation ($1$ tuple inserted); and 4) a delete that removes 1 randomly chosen tuple. Figure 15 shows the results for $U20$ varying history size ($H10$ to $H1000$). The results indicate that performance is comparable to performance for updates.

**TPC-C.** In this experiment, we compute provenance for the TPC-C OLTP benchmark. We executed a TPC-C transactional workload over an instance with 32 warehouses. The resulting database is roughly 16GB large. The benchmark defines 5 transaction types, out of which 2 are read-only. We compared the $N$ and $PM$ methods for the 3 transaction types that execute updates. Figure 16 shows the results for computing the provenance of a single transaction of each type. Each of these transactions only manipulate a few tuples each. Thus, the cost for $PM$ is quite low. The cost for $N$ is dominated by scanning large input relations (millions of tuples).

### 9.3 History and Audit Logging Overhead

We use audit logging and time travel to reconstruct provenance of past transactions. We now quantify the runtime and storage overhead of DBMS X’s built-in temporal and audit features. We measure the execution time of 10,000 transactions with $U10$ and $T1$ run over the $R1000$ instance. The table below shows the total runtime for three configurations: without temporal and audit logging features ($W/O$), with temporal features, and with both the temporal and audit logging features. If history maintenance is activated then this results in about 12% runtime overhead for this workload. This seems to align with the performance numbers from DBMS X’s documentation which states 5% overhead for mixed read-write workloads. Activating audit logging in addition results in a total overhead of $\sim 19\%$.

<table>
<thead>
<tr>
<th></th>
<th>W/O</th>
<th>History</th>
<th>History+Audit</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>27.46 sec</td>
<td>30.94 sec</td>
<td>32.59 sec</td>
</tr>
</tbody>
</table>

Tuples in the relation without history are 21 byte large. Activating time travel results in an overhead of 37 bytes for currently valid tuples. Outdated tuple versions occupy 65 bytes on average. The average audit log entry size is 378 bytes (per executed statement).

### 9.4 Eager Provenance Computation

We now compare our approach with eager provenance computation during transactions execution. We consider two configurations: 1Step stores a separate provenance record for each tuple version and statement in an extra relation. Each such record is linked to the provenance record for the previous version of the tuple. The provenance of a transaction is reconstructed by recursively joining these provenance records; Full stores the complete derivation history of each tuple in an additional column.

**Transaction Execution Overhead.** Using the workload from Section 9.2 we compare the overhead for transaction execution incurred by these two eager methods with our method (Reenact). The results are shown in Figure 18. The performance of our method and 1Step remains stable when increasing the size of the history. In contrast the overhead of Full increases with the history size, because the size of provenance per tuple increases and the attribute storing provenance has to be updated by every operation. Both 1Step and Full do significantly slow down transaction processing showing a factor 7 higher overhead than our approach.

**Storage Size.** We compare the storage size used by the three methods for a table with 1M rows varying the size of the history ($H10$, $H100$, and $H1000$) and number of tuple affected by each update ($T1$, $T10$, and $T100$). For our method we show the total storage space as well as the breakdown into regular relation plus history and the audit log. Only the size of the audit log is affected by the $T$ parameter. Thus, we only show our method for $T10$ and $T100$ since the other methods require the same storage for all $T$ values. The results
shown in the table below demonstrate that in the worst case (1 tuple affected per update) our method requires up to ~4 times more storage than the best approach. This overhead is caused by the audit log storing one SQL statement per modified tuple. However, if more tuples are affected by each statement then our method requires about the same or less storage space than the alternatives. Note that in other two approaches, there is no record of the SQL statements that were executed.

<table>
<thead>
<tr>

<tr>
<td>Total</td>
</tr>
</tbody>
</table>

Retrieving Provenance. We now compare the performance of reenactment (the PM method) for retrieving provenance with 1Step and Full. Figure 17 shows the result for computing provenance of transactions with U10 and T1 varying the history size (H). We created relevant indexes for each method. Optimized reenactment outperforms both alternatives, because Full requires filtering tuples based on the transaction identifier contained in the attribute storing the provenance and 1Step requires a recursive query or multi-way join to reconstruct the provenance of a transaction from provenance for each update.

9.5 Summary

Our evaluation confirms the efficiency and scalability of our approach - the presented techniques for retroactively computing provenance scale to relations with millions of tuples, large transactions (1000 update statements), large number of updated tuples, and large histories. The proposed optimizations increase performance by several orders of magnitude. The runtime overhead for transaction execution incurred by our approach due to auditing and history maintenance is below 20% for our experimental workloads - a small price to pay compared to eager materialization of provenance while transactions are executed (about 133% and higher).

10 Conclusions

We have presented the first solution for computing the provenance of transactions run under SI. Our approach is based on the novel concept of reenactment queries, i.e., queries that simulate the effect of updates and transactions. We have extended the semiring annotation framework with updates and transactional semantics using version annotations. Using audit logging, time travel, and a relational encoding of reenactment we can retroactively compute the provenance of tuples produced by transactional histories using a standard DBMS. Our experiments confirm that our implementation scales to large databases, histories, and transactions. In future work, we will study reenactment for other concurrency control protocols and more expressive query languages (e.g., aggregation). Reenactment has many potential applications such as answering historic What-If queries (e.g., “What would have happened if we had updated accounts using 10% interest?”).

B Proofs

**Theorem 5.1** Let $h : \mathcal{K} \rightarrow \mathcal{K}'$ be a semiring homomorphism, then $h$ commutes with any $Q$ in the above algebra if $h$ is applied to $Q$. Let $I$ be a $\mathcal{K}$ database instance. Then, $h(Q)(h(I)) = h(Q(I))$

**Proof** We only need to show that the theorem holds for the new operator $Q = \{ t \rightarrow k \}$. The result of this operator is a relation $R$ with $R(t') = 0$ for $t' \neq t$ and $R(t) = k$. Applying the homomorphism to $R$ we get a singleton relation $R(t) = h(k)$. Applying the homomorphism to $Q$ we get $h(Q) = \{ t \rightarrow h(k) \}$. Evaluating this query we get the singleton relation $R(t) = h(k)$ as well.

**Theorem 5.2** $h_U$ is a surjective semiring homomorphism.

**Proof** Note that $h_U$ evaluates the symbolic expression of an representative $k$ of a congruence class $[k]_{\sim}$. To prove that $h_U$ is well-defined we have to show that $k \equiv_{\sim} k' \Rightarrow h_U(k) = h_U(k')$, i.e., all representative of a congruence class are mapped to the same element of $K$. If $k \equiv_{\sim} k'$ then there has to exist at least one sequence of applications of the equivalences that define the congruence relation of $K^\nu$ (Figure 3) such that applying this sequence to $k$ we get $k'$. We prove the implication by induction over these equivalences. Most of these equivalences follow directly from the construction of $h_U$ and the definition of $\text{MV}$ equivalences:

### Laws of commutative semirings

- $h_U(k + 0_K) = h_U(k) +_K h_U(0_K)$
- $h_U(k \times 1_K) = h_U(k) \times_K h_U(1_K)$

### Equivalences involving version annotations

- $h_U(\mathcal{A}(0_K)) = h_U(0_K) = 0_K = h_U(0_K)$
- $h_U(\mathcal{A}(k + k')) = h_U(k + k') = h_U(k) +_K h_U(k')$
- $h_U(\mathcal{A}(k \times k')) = h_U(k) \times_K h_U(k')$

In the second case if $\mathcal{A} \neq D_{\nu}^{id}$ we get:

- $h_U(\mathcal{A}(k + k')) = h_U(k + k') = h_U(k) +_K h_U(k')$
- $h_U(\mathcal{A}(k) + \mathcal{A}(k')) = h_U(\mathcal{A}(k) + \mathcal{A}(k'))$
Thus, \( h_U \) is well-defined and for the remainder of the proof it suffices to restrict the discussion to single representatives of congruence classes.

We now prove that \( h_U \) is surjective. Consider an arbitrary element \( k \in K \). By construction of \( K^\nu \), \( k \in K^\nu \). We have \( h_U(k) = k \) and, thus, \( h_U \) is surjective.

It remains to be shown that \( h_U \) is a semiring homomorphism. We have to show that \( h_U(0_{K^\nu}) = 0_K \), \( h_U(1_{K^\nu}) = 1_K \), \( h_U(k + k') = h_U(k) +_K h_U(k') \) and \( h_U(k \times k') = h_U(k) \times_K h_U(k') \). Recall that \( 0_{K^\nu} = [0_K] \sim \) and \( 1_{K^\nu} = [1_K] \sim \). As proven above we can choose an arbitrary representative of a congruence class when applying \( h_U \). We get \( h_U(0_{K^\nu}) = h_U(0_K) = 0_K \) and analog \( h_U(1_{K^\nu}) = h_U(1_K) = 1_K \). Furthermore, \( h_U(k + k') = h_U(k) +_K h_U(k') \) and \( h_U(k \times k') = h_U(k) \times_K h_U(k') \) trivially hold based on the definition of \( h_U \). Thus, \( h_U \) is a semiring homomorphism.

**Theorem 5.3** Any semiring homomorphism \( h : K_1 \rightarrow K_2 \) can be lifted to a homomorphism \( h^\nu : K_1^\nu \rightarrow K_2^\nu \) as defined below. If \( h \) is surjective then so is \( h^\nu \).

\[
h^\nu(k) = \begin{cases} 
  (h(k)) & \text{if } k \in K_1 \\
  A(h^\nu(k')) & \text{if } k = A(k') \\
  h^\nu(k_1) + h^\nu(k_2) & \text{if } k = k_1 + k_2 \\
  h^\nu(k_1) \times h^\nu(k_2) & \text{if } k = k_1 \times k_2 
\end{cases}
\]

**Proof** Note that the mapping \( h^\nu \) is applied to a representative of a congruence class. We need to prove that if \( k \equiv k' \) then \( h^\nu(k) \equiv h^\nu(k') \). Note that \( K_1^\nu \) and \( K_2^\nu \) are using the same congruence relations with the exception of evaluating expressions with operands from \( k \)-structures of expressions, the implication holds as long as \( \nu \) is a semiring homomorphism. If \( k \equiv k' \), then \( h^\nu(k) \equiv h^\nu(k') \). For elements from \( K_2 \) we have \( k \equiv k' \) because there are no equivalences in the congruence relation that equate elements from \( K_2 \). Thus, \( h^\nu(k) = h(k) = h(k') = h^\nu(k') \) and we get \( h^\nu(k) \equiv h^\nu(k') \).

Since the symbolic expressions of \( K_1^\nu \) and \( K_2^\nu \) are generated by the same grammar with the exception that \( k \) is a \( K_2 \)-structure of expressions, the implication holds as long as \( h^\nu \) is a semiring homomorphism. If \( k \equiv k' \) then \( h^\nu(k) \equiv h^\nu(k') \). For the same reason, surjectivity of \( h^\nu \) implies surjectivity of \( h \). For an expression \( k_2^\nu \), let \( k_1 \) be the elements from \( K_2 \) that occur in this expression. Given that \( h \) is surjective we can find \( l_1 \) to \( l_n \) in \( K_1 \) such that \( h(l_i) = k_i \). Now we construct an element \( k_1^\nu \) with the same structure as \( k_2^\nu \), but with \( l_i \) instead of \( k_i \) for \( i \in \{1, \ldots, n\} \). From the constructions and definition of \( h^\nu \) follows that \( h^\nu(k_1^\nu) = k_2^\nu \). It remains to be shown that \( h^\nu \) is a homomorphism.

\[
\begin{align*}
  h^\nu(k_1 + k_2) &= h^\nu(k_1) + h^\nu(k_2) & \text{(by construction)} \\
  h^\nu(k_1 \times k_2) &= h^\nu(k_1) \times h^\nu(k_2) & \text{(by construction)} \\
  h^\nu(0) &= 0 & (h(0) = 0 \text{ and } k \equiv h^\nu(k) \equiv h^\nu(k')) \\
  h^\nu(1) &= 1 & (h(1) = 1 \text{ and } k \equiv h^\nu(k) \equiv h^\nu(k')) \\

\end{align*}
\]

**Theorem 5.4** Let \( h^\nu \) be a lifted homomorphism as defined in Theorem 5.3, \( h^\nu \) commutes with updates.\[\]

**Proof** We have to show for each update operation that \( h^\nu(u(R)) = u(h^\nu(R)) \). Recall that any lifted homomorphism is history preserving, i.e., it keeps the structure of expressions intact.

**Update:**

\[
h^\nu\left[U[\theta, A, T, \nu](R)(t)\right] = h^\nu\left(R(t) \times (-\theta)(t)\right) + \sum_{u:u.A=t} \sum_{i=0}^{n(R(u))} U^\nu_{T,\nu} [U[\theta, A, T, \nu](u)[i]](R(u)[i]) = \theta(u)
\]

Since \( h^\nu \) is a homomorphism it commutes with semiring operations and we get:

\[
h^\nu\left(R(t) \times (-\theta)(t)\right) + \sum_{u:u.A=t} \sum_{i=0}^{n(R(u))} U^\nu_{T,\nu} [U[\theta, A, T, \nu](u)[i]](R(u)[i]) \times \theta(u) = U[\theta, A, T, \nu](h^\nu(R))(t)
\]

Note that application of a lifted homomorphism such as \( h^\nu \) to a normalized annotation does not change the structure of summands in this annotation, i.e., \( h^\nu \) can be pushed into this sum.

\[
h^\nu\left(R(t) \times (-\theta)(t)\right) + \sum_{u:u.A=t} \sum_{i=0}^{n(R(u))} U^\nu_{T,\nu} [U[\theta, A, T, \nu](u)[i]](R(u)[i]) \times \theta(u) = U[\theta, A, T, \nu](h^\nu(R))(t)
\]

**Inserts:**

\[
h^\nu\left[I[Q, T, \nu](R)(t)\right] = h^\nu\left(R(t) + \sum_{i=0}^{n(Q(D))} U^\nu_{T,\nu} [I[Q, T, \nu](Q(D)(t))\right] = h^\nu\left(R(t) + h^\nu\left(I[Q, T, \nu](Q(D)(t))\right)\right)
\]
Recall that based on the construction of \( h^\nu \) it follows that \( h^\nu(I_{T,v+1}^d(k)) = I_{T,v+1}^d(h^\nu(k)) \). Furthermore, since \( h^\nu \) is a homomorphism it commutes with queries. Thus,

\[
\begin{align*}
&= h^\nu \left( R(t) \right) + I_{T,v+1}^d(Q(h^\nu(D))(t)) \\
&= I(Q(T,T,\nu)(h^\nu(R)))(t)
\end{align*}
\]

Delete:

\[
\begin{align*}
h^\nu \left( D[\theta,T,\nu](R)(t) \right) \\
&= h^\nu \left( R(t) \right) - \theta(t) \\
&\quad + \sum_{i=0}^{n(R(t))} D_{T,v+1}^d(R(t)[i]) \times \theta(t) \\
&= h^\nu \left( R(t) \right) - \theta(t) \\
&\quad + \sum_{i=0}^{n(h^\nu(R)(t))} h^\nu(id)(h^\nu(R)(t)[i]) \quad (R(t)[i]) \times \theta(t) \\
&= D[\theta,T,\nu](h^\nu(R))(t)
\end{align*}
\]

Comms:

\[
\begin{align*}
h^\nu \left( C[T,\nu](R)(t) \right) \\
&= h^\nu \left( \sum_{i=0}^{n(R(t))} \text{COM}[T,\nu](R(t)[i]) \right) \\
&= \sum_{i=0}^{n(h^\nu(R)(t))} h^\nu \left( \text{COM}[T,\nu](R(t)[i]) \right)
\end{align*}
\]

where

\[
\text{COM}[T,\nu](k) = \begin{cases} 
C_{T,v+1}^d(k) & \text{if } k = I/U \cup D_{T,v'}^d(k') \\
& \text{else}
\end{cases}
\]

so if \( R(t) = I/U \cup D_{T,v'}^d(k') \) then

\[
\begin{align*}
h^\nu \left( \text{COM}[T,\nu](R(t)) \right) \\
&= h^\nu \left( C_{T,v+1}^d(R(t)) \right) \\
&= h^\nu \left( \text{COM}[T,\nu](h^\nu(R)(t)) \right) \\
&= \text{COM}[T,\nu](h^\nu(R)(t))
\end{align*}
\]

otherwise we get

\[
\begin{align*}
h^\nu \left( \text{COM}[T,\nu](R(t)) \right) \\
&= h^\nu \left( R(t) \right) \\
&= h^\nu(R)(t) \\
&= \text{COM}[T,\nu](h^\nu(R))(t))
\end{align*}
\]

In summary \( h^\nu(\text{COM}[T,\nu](R(t))) = \text{COM}[T,\nu](h^\nu(R)(t)). \)

Thus,

\[
\begin{align*}
n(h^\nu(R)(t)) \\
&= \sum_{i=0}^{n(h^\nu(R)(t))} h^\nu \left( \text{COM}[T,\nu](R(t)[i]) \right) \\
&= \sum_{i=0}^{n(h^\nu(R)(t))} \text{COM}[T,\nu](h^\nu(R)(t)[i]) \\
&= \text{COM}[T,\nu](h^\nu(R))(t)
\end{align*}
\]

\textbf{Theorem 5.5} Let \( h^\nu \) be a lifted homomorphism (Theorem 5.3). \( h^\nu \) commutes with histories.

\textbf{Proof} As was demonstrated before, \( h^\nu \) commutes with updates and, thus also sequences of updates. Thus, for single transactions the theorem holds. Specifically, for any update \( u \) in a transaction \( T \) executed at \( \nu \) we have

\[
\begin{align*}
h^\nu(R[T,\nu]) = h^\nu(u(R[T,\nu]))
\end{align*}
\]

It remains to be shown that \( h^\nu \) commutes with the computation of \( R[\nu] \) over the results of past transactions, i.e., applying \( h^\nu \) to the result of this computation is the same as applying it to every input \( R[T,\nu] \) of the computation. By iteratively pushing the homomorphism through all transactions involved in a history the result follows.

\[
\begin{align*}
h^\nu(R[\nu](t)) \\
&= h^\nu \left( \sum_{T \in H \land \text{End}(T) < \nu} R[T,\nu](t) \times \text{validAt}(T,t,R[T,\nu](t)[i],\nu) \right) \\
&= \sum_{T \in H \land \text{End}(T) < \nu} \sum_{i=0}^{n(h^\nu(R[T,\nu](t)))} h^\nu \left( \text{validAt}(T,t,R[T,\nu](t)[i],\nu) \right)
\end{align*}
\]

Since \( h^\nu(1) = 1 \) and \( h^\nu(0) = 0 \) we know that

\[
\begin{align*}
h^\nu \left( \text{validAt}(T,t,R[T,\nu](t)[i],\nu) \right) \\
&= \text{validAt}(T,t,R[T,\nu](t)[i],\nu)
\end{align*}
\]

It remains to be shown that

\[
\begin{align*}
\text{validAt}(T,t,R[T,\nu](t)[i],\nu) \\
&= \text{validAt}(T,t,h^\nu(R[T,\nu])(t)[i],\nu)
\end{align*}
\]
under the assumption $h^\nu(R[T, \nu(t)][i]) \neq 0$ (otherwise the value of VALIDAT is irrelevant). Since $h^\nu$ does not affect version annotations $k = C^\nu_{T, \nu}(k') \Rightarrow h^\nu(k) = C^\nu_{T, \nu}(h^\nu(k')).$

$\text{VALIDAT}(T, t, h^\nu(k), \nu) = 1$

$\Leftrightarrow h^\nu(k) = C^\nu_{T, \nu}(h^\nu(k'))$

$\land (\exists T' \neq T : \text{End}(T') \leq \nu$

$\land \text{updated}(T', t, h^\nu(k)))$

$\Leftrightarrow k = C^\nu_{T, \nu}(k')$

$\land (\exists T' \neq T : \text{End}(T') \leq \nu$

$\land \text{updated}(T', t, k))$.

We now have to prove that $\text{updated}(T', t, h^\nu(k)) \Leftrightarrow \text{updated}(T', t, k)$.

$\text{updated}(T, t, h^\nu(k))$

$\Leftrightarrow \exists u \in T, t, i, j : h^\nu(R[T, \nu(u)])(t)[i] = h^\nu(k)$

$\land h^\nu(R[T, \nu(u) + 1])(t')[j] = h^\nu(U/D^\nu_{T, \nu(u) + 1}(k))$

$\Leftrightarrow \exists u \in T, t, i, j : R[T, \nu(u)](t)[i] = k$

$\land R[T, \nu(u) + 1](t')[j] = U/D^\nu_{T, \nu(u) + 1}(k)$

The last equivalence follows from the fact that we have proven that $h^\nu$ commutes with the operations of one transaction above.

**Theorem 6.1.** Let $u$ be an update and $R(u)$ its reenactment query. Then, $u \equiv_{[X\theta]} R(u)$.

**Proof.** Proven by substitution of the definitions of update operations, queries, and annotation operators. We show the proof for an update $u = U[\theta, A, T, \nu](R)$. The reenactment query $R(u)$ for $u$ is:

$s_u, T, \nu + 1(\Pi_A(\sigma_\theta[R[T, \nu]])) \cup \sigma_\neg\theta[R[T, \nu]]$

We have to show that $u(t) = R(u)(t)$ for any $t \in R$. Let $Q^\prime = \Pi_A(\sigma_\theta[R[T, \nu]])$. Substituting $\mathcal{R}A^\nu$ definitions we get:

$R(u)(t) = \sum_{i=0}^{n(Q^\prime(u))} U_{T, \nu + 1}^{id}(Q^\prime(u)[i]) (Q^\prime(u)[i]) + (R(t) \times \neg\theta(t))$

Now we substitute $Q^\prime(t) = \sum_{u, A = t} (R(u) \times \theta(u))$ and apply commutativity of $+ \text{ of } t$ to get:

$= R(t) \times \neg\theta(t)$

$\sum_{i=0}^{n(Q^\prime(u))} U_{T, \nu + 1}^{id}(Q^\prime(t)[i]) (\sum_{u, A = t} R(u) \times \theta(u))[i])$

Using the MV-semiring equivalence $A(k \times k') = A(k) \times A(k')$, we can pull out the inner sum:

$= R(t) \times \neg\theta(t)$

$\sum_{u, A = t} n(R(u) \times \theta(u)) U_{T, \nu + 1}^{id}(R(u)[i]) ((R(u) \times \theta(u))[i])$

Note that $n(R(u) \times \theta(u)) = n(R(u))$ if $\theta(u) = 1$. If $\theta(u) = 0$ then $n(R(u) \times \theta(u)) \neq n(R(u))$, but this does not affect the result, because then each $R(u)[i] \times \theta(u) = 0$. An analogous argument holds for $id(R(u) \times \theta(u))$. Applying the distributive laws for semirings, we get:

$= R(t) \times \neg\theta(t)$

$\sum_{u, A = t} n(R(u)) U_{T, \nu + 1}^{id}(R(u)[i] \times \theta(u))$

Using the MV-semiring equivalence $A(k \times k') = A(k) \times A(k')$ if $k' = 1$ or $k' = 0$ we can pull out the multiplication $\theta(u)$ to get:

$= R(t) \times \neg\theta(t)$

$\sum_{u, A = t} n(R(u)) U_{T, \nu + 1}^{id}(R(u)[i]) \times \theta(u)$

$= U[\theta, A, T, \nu](R(t))$

The proofs for inserts and deletes are analogous.

**Theorem 6.1.** Let $T$ be a transaction and $R(T)$ its reenactment query. Then, $T \equiv_{[X\theta]} R(T)$

**Proof.** We prove the theorem by induction over the number of updates in transaction $T$. For simplicity, we assume that $T$ updates a single relation $R$. The proof can easily be extended for transactions that update multiple relations.

**Induction Start:** For a transaction with a single update $u_1$, the theorem follows from the equivalence result for updates and a simple argument for the equivalence of the annotation operator for commits and commit annotations produced by $T$.

**Induction Step:** Assume that we have proven that reenactment is annotation equivalent for transactions with up to $i$ updates. We have to show that the same holds for any $T = u_1, \ldots, u_i, u_{i+1}$. Let $T_i = u_1, \ldots, u_i, c$. In the induction start we have already proven that the commit operation of a transaction are equivalent to the commit annotation operator in its reenactment query. Thus, we ignore the existence of commit operations in the following proof. WLOG assume $\text{End}(T) = \text{End}(T_i)$. We know that $R(T_i) \equiv_{[X\theta]} R[T_i, \nu(u_i + 1)] = R[T_i, \nu(u_i) + 1]$. Since $T_i$ and $T$ have executed the same updates over the same input it follows that $R[T_i, \nu(u_i + 1) + 1] = R[T, \nu(u_i) + 1]$. From the definition of historic databases we know that $R[T, \nu(u_i + 1) + 1] = u_{i+1}(R[T, \nu(u_{i+1})])$. Using the equivalences stated
above we can deduce $u_{i+1}(R(T, \nu(u_{i+1}))) \equiv_{N[X]} u_{i+1}(R(R(u_i)))$. We know that $R(u_{i+1}) \equiv_{N[X]} u_{i+1}$ and, thus, it follows that $R(T, \nu(u_{i+1})) \equiv_{N[X]} R(R(u_{i+1}))$. Since $R(R(u_{i+1})) = R(R(T))$, this concludes the proof.

**Theorem 6.3** For $Q$ and $Q'$ to be two $\mathcal{RA}^+\nu$ queries and $K$ a naturally ordered semiring. Then

\[ Q \equiv_{\mathcal{K}^\nu} Q' \Rightarrow Q \equiv_{\mathcal{K}^\nu} Q' \]

Let $Q$ and $Q'$ be two $\mathcal{RA}^{+/\nu}$ queries or updates and $K$ a naturally ordered semiring, then

\[ Q \equiv_{N[X]} Q' \Rightarrow Q \equiv_{\mathcal{K}^\nu} Q' \]

**Proof** Let $K_1$ and $K_2$ be naturally ordered semirings. It was proven in [18] that $Q \equiv_{N[X]} Q' \Rightarrow Q \equiv_{K_2} Q'$. Furthermore, $Q \equiv_{K_1} Q' \Rightarrow Q \equiv_{K_2} Q'$ if there exists a surjective semiring homomorphism $K_1 \to K_2$. The first part of the theorem follows from the fact that $\text{Unv}$ is a surjective semiring homomorphism (Theorem 5.2) and that the property of being naturally ordered is preserved for $\mathcal{K}^\nu$ semirings (see Lemma B.2 below).

The second parts hold if we can demonstrate that 1) if $K$ is naturally ordered then so is $K^\nu$, 2) a lifted homomorphism $h^\nu$ is surjective if $h$ is surjective and commutes with updates, the annotation operator, and histories. In particular, since any valuation $\chi : X \to K$ can be uniquely extended to a homomorphism $\text{Eval}_\chi : N[X] \to K$ [19], 1) and 2) imply the second part. As mentioned above 1) is proven in Lemma B.1. The lifting of homomorphisms was shown to preserve surjectivity (Theorem 5.3) and these homomorphisms commute with updates (Theorem 5.3) and histories (Theorem 5.5). The fact that $h^\nu$ commutes with the annotation operator is proven in Lemma B.2.

**Lemma B.1** Let $K$ be a naturally ordered semiring, then $K^\nu$ is naturally ordered.

**Proof** Let $K$ be a naturally ordered semiring, i.e., the natural order: $k \leq k' \Leftrightarrow \exists k'' : k + k'' = k'$ is a partial order. Recall that for a relation $\leq$ to be a partial order it has to be reflexive, antisymmetric, and transitive. Consider the natural order on $K^\nu$. Reflexivity follows from $k + 0 = k$. Transitivity holds because $k_1 \leq k_2 \land k_2 \leq k_3 \Rightarrow 3k'_1, k'_2 : k_1 + k'_1 = k_2 + k'_2 = k_3 \Rightarrow k_1 + k'_1 + k'_2 = k_3$. Now let $k_{13} = k'_1 + k'_2$. We get $k_1 + k_{13} = k_3 \Rightarrow k_1 \leq k_3$. Thus, it remains to be shown that $\leq$ is antisymmetric. We prove this fact by demonstrating that there are no additive inverses in $K^\nu$, i.e., the operation of adding an element $k'$ to an element $k$ cannot be inverted by another addition. If this property holds then $\leq$ has to be antisymmetric.

Consider two elements $k$ and $k'$ of $K^\nu$ in normal form (a sum of elements that do not contain addition). Let $k_1, \ldots, k_m$ be the summands in $k$ and $k'_1, \ldots, k'_m$ be the summands in $k'$. WLOG consider $m = 1$, because if an additive inverse can be found for the sum of $k'_1, \ldots, k'_m$ then there has to exist an inverse for each element $k'_i$. Treat every summand as an ordered tree whose leaves are elements of $K$ and $x$-operations are considered n-ary. Furthermore, order operands of such monomials as follows: 1) elements of $K$ precede any elements wrapped in version annotations and are ordered based on an arbitrary extension of the natural order of $K$ to a total order; 2) elements wrapped in version annotations are ordered based on some order over $A$ based on the outermost version annotation; 3) two elements with the same version annotation are ordered based on the order of their children.

For example, for $A_1(A_2(x_1) \times x_2 \times A_2(x_3))$ assuming $x_1 < x_2 < x_3$ in the extension of the natural order on $N[X]$ we would order the elements of the monomial as follows: $A_1(x_2 \times A_2(x_1) \times A_2(x_3))$. We now prove that inverses for an element $k'$ cannot exists by induction over the structure of such summands (trees).

Let $k_\nu \neq 0$ be the element we are trying to invert and $-k_\nu$ represent its inverse (if it exists).

**Base case**: Consider trees of height 1, i.e., $k_\nu = k \neq 0$ with $k \in K$. If $-k_\nu = -k$ with $-k \in K$ then this leads to a contradiction since $K$ is naturally ordered. To see why this is true consider, $k + -k = 0$ which would imply $k \leq 0$, but also $0 + k = k$ which implies $0 \leq k$. Since we have $k \neq 0$ this yields the contradiction. Thus, if an inverse $-k_\nu$ exists it must contain at least one version annotation. However, it can be shown by induction over equivalences of the congruence relation of $K^\nu$ that by adding a summand with a version annotation to an element of $K$ can never yield 0 as a result.

**Inductive step**: Assume that for any tree of depth up to $n$ we have proven that no inverse exists. Consider $k^{n+1} \neq 0$ as an element whose tree is of height $n + 1$. We have to distinguish two cases: either $k^{n+1} = A(x^n)$ for some tree $x^n$ of depth $n$ or $k^{n+1} = \prod_{i=1}^{m} k_i$ where each $k_i$ is of maximal depth $n$ and no inverse exists for any of these $k_i$.

**Case 1** ($k^{n+1} = A(x^n)$): Note that the congruence relation of $K^\nu$ does not manipulate individual version annotations. Thus, $-k^{n+1}$ would have to be of the form $A(-x^n)$ such that $A(x^n) + A(-x^n) = A(x^n - x^n) = A(0) = 0$. However, this leads to a contradiction because $k^n$ is of depth $n$ and thus no additive inverse of $k^n$ can exist.

**Case 2** ($k^{n+1} = \prod_{i=1}^{m} k_i$): We prove this case by induction over $m$. If $m = 2$ then $k^{n+1} = k_1 \times k_2$ and WLOG we have to distinguish 2 cases: 1) $k_1 = A(k'_1)$ and $k_2 \in K$ or 3) $k_1 = A(k'_1)$ and $k_2 = (k'_2)$. Note that $k_1, k_2 \in K$ conflicts with the fact that $k^{n+1}$ is of height
$n + 1$ and, thus, we do not have to consider this case. In any case we can construct $-k^{n+1}$ as either $-k_1 \times k_2$ or $k_3 \times -k_2$. For any $k \in \mathbb{K}$ no inverse exists. Thus, we have to find the inverse of an element $k_i = A(k'_i)$. However, since $k_i$ of height less than $n$ we know that none such inverse exists. The inductive step is analog.

**Lemma B.2** Let $h^\nu$ be a lifted semiring homomorphism (as defined in Theorem 5.3). $h^\nu$ commutes with the annotation operator $\alpha$.

**Proof**

$$h^\nu(\alpha_{U/D,T,\nu}(R)(t)) = h^\nu\left( \sum_{i=0}^{n(R(t))} U/D_{T,\nu}(R(t)[i]) \right)$$

For commits recall that

$$h^\nu(\text{com}(T,\nu)(k)) = \text{com}(T,\nu)(h^\nu(k))$$

and thus $h^\nu(\alpha_{C,T,\nu}(R)(t)) = \alpha_{C,T,\nu}(h^\nu(R))(t)$.

For inserts consider that $id_{new} = id(T,\nu,t,k)$.

$$h^\nu(\alpha_{I,T,\nu}(R)(t)) = h^\nu\left( \sum_{i=0}^{n(R(t))} I_{T,\nu}^{id_{new}}(R(t)[i]) \right)$$

**Theorem 7.1** The $\text{Rel}(R[T])$ operation is lossless.

**Proof** We prove the theorem by induction over the number of operations in a transaction. Recall that $R[T]$ is derived from $R[T] End(T)$ by applying $\text{filt}(t)$.

**Base Case:** Consider a transaction $T = u, c$ with one operation $u$. We have to prove that $R[T](t)$ can be recovered from $\text{Rel}(R[T])$ for any $t$. We treat each of the three types of update operations separately.

$u = U[\theta, A, T, \nu](R)$: Consider $R[T](t) = \sum_{i=0}^{n(R[T])} R[T][i]$, the annotation of one tuple $t$ in $R[T]$ and let $k_i$ denote $R[T, End(T)][i]$. Note that each such $k_i$ is guaranteed to be of the form $C^u_{T, End(T)}(U^{id}_{T,\nu}(u))C^u_{T, End(T)}(k'_i)$ with $k'_i \in \mathbb{K}$ and $T' \neq T$. This fact follows immediately from the definition of $\text{filt}(t)$ which removes summands that are wrapped in version annotations of other transactions and replaces subexpressions of the form $C^u_{T', End(T')}(k)$ with $C^u_{T', End(T')}(x_{id})$ if $T' \neq T$. Since $T = u, c$ every summand is bound to be structured like this.

Now consider the schema created for $R[T]$. Applying the definition shown in Figure 9, the schema is $\text{Sch}(R) \supset \text{P}(R) \supset \text{U} \supset \text{U}_c$ where $\text{P}(R)$ contains attributes $X{id}, I, D, V$ and a provenance renaming of the attributes of $R$. The attribute name of $U_t$ encodes $\nu(u_1)$ and the type of the update. The attribute name of $U_c$ encodes $\text{End}(T)$. According to the definition of $\text{Rel}(R[T])$ every summand in the annotation of tuple $t$ is encoded as a separate tuple $t \supset \text{Rel}(\text{End}(T)) \supset R[T](t)[i]$. Applying the definition of $\text{Rel}(\text{End}(T)) \supset R[T](t)[i]$, a summand $C^u_{T, End(T)}(U^{id}_{T,\nu}(u))C^u_{T, End(T)}(x_{id})$ would be encoded as $t \supset T' \supset \text{End}(T') \supset id \supset \nu(x_{id}) \supset \text{true} \supset \text{true}$. From $T'$, $\text{End}(T')$ and $id$ we can directly reconstruct $C^u_{T', \text{End}(T')}(x_{id})$. Based on the value $U_t$ ($\text{true}$) and $\nu(u_1)$ and the type of the update ($U$) encoded in the name $U_t$ it can be determined that the element we have constructed so far should be wrapped in $U^{id}_{T,\nu}(u)$. Finally, $\text{End}(T)$ is determined based on the name of $U_c$.

$u = I(Q(R_1, \ldots, R_n), T, \nu)(R)$: Let $k_i$ denote individual summands in $R[T](t)$ as in the previous case. Every summand $k_i$ is of the form $C^u_{T, End(T)}(P_{R}(x_{id}(k_{i-1} \times \ldots \times k_{i_0})))$ with $k_{i_0} = 1, k_{i_1} = C^u_{T, End(T)}(x_{i_0})$, or $k_{i_0} = x_{i_0}$. Note that $n$ is number of (not necessarily distinct) relation mentions and constant relation operators in $Q$, e.g., in $Q = R \times R \times R$ we have $n = 3$. Applying the definition of $\text{Sch}(\text{Rel}(R[T]))$ each $k_i$ would be encoded using $P(R) \supset A_1 \supset \ldots \supset A_n$ where each $A_j = P(R_j)$ for an relation access $R_j$ or $A_j = \text{const}$ for a constant relation operator. Recall that repeated attribute names have been disambiguated by $\text{Id}_{P}$. The version annotation for $u$ can be reconstructed as explained above for updates. The attributes of $P(R)$ are guaranteed to be null since all tuple versions in $R[T]$ have been created by $u$. Based on the definition of $\text{Rel}(t)$ if $k_{i_1} = 1$ then the attributes in $P(R_j)$ respective the $\text{const}$ attribute are null else these attributes store $T'$, $\text{End}(T')$ and $id'$ such that $C^u_{T', \text{End}(T')}(x_{id})$ can be reconstructed analog to the update case or store $id'$ (in case of the constant relation operator) and $x_{id}$ can be recovered. Then $k_i$ is reconstructed by multiplying the individual reconstructed operands and wrapping the result in $I^{id}_{T,\nu}(u)$ where $id'$ is determined using $f_{id}$ as explained in Sec-
$u = D[\theta, T, \nu](R)$: The case for delete is analogous to the case for updates.

**Inductive Step:** Let $T = u_1, \ldots, u_{n+1}, c$ and assume that any annotation produced by a transaction of length up to $n$ can be recovered from its relational encoding. We now show that the same holds for $T$. We distinguish between three cases based on whether the last operation is an update, insert, or delete.

- **Update Case:** Let $u_{n+1} = U[\theta, A, T, \nu](R)$: Consider $R[T](t) = \sum_{i=0}^{n|R[T]|} (R[T][\theta](1))$ the annotation of one tuple $t$ in $R[T]$ and let $k_i$ denote $R[T, End(T)][t]$. Note that each such $k_i$ is guaranteed to be of the form $C_{T,End(T)}^{id}(k'_i)$ or $C_{T,End(T)}^{rev}(k'_i)$ where each $k'_i$ is an annotation produced by a sequence of up to $n$ updates. Thus, if we ignore the commit annotation then $k'_i$ could have been produced by a transaction with up to $n$ updates. Since the definition of the schema $Sch_{End(T)}(T, R)$ and relational encoding $Rel(End(T))$ is recursively defined based on the schema and relational encoding for the first $n$ updates, we know that $k'_i$ can be reconstructed. Specifically, $Sch_{End(T)}(T, R) = Sch(R) \triangleright ID_{rel}(Sch^{u_{n+1}}(T, R) \triangleright U_{n+1}) \triangleright UC$. If the version annotation for $u_{n+1}$ is present in $k_i$ then according to the definition of $Rel()$ attribute $U_{n+1}$ would be set to true. Based on the induction hypothesis we can reconstruct $k'_i$ and then use the value of this attribute to determine whether $U_{T,\nu}(u)$ should be added or not.

- **Insert Case:** Let $u_{n+1} = I[Q, T, \nu](R)$: Every summation $k_i$ in an annotation is either of the form 1) $C_{T,End(T)}^{id}(I_{T,\nu}(u)(k_1 \times \ldots \times k_{n}))$ with $k_{i_{j}} = 1, k_{i_{j}} = C_{T,End(T)}^{id}(k'_i)$, or $k_{i_{j}} = x_i$ (if produced by a constant relation operator) where $m$ is the number of relation mentions and constant relation operators in $Q$; or 2) $C_{T,End(T)}^{rev}(k'_i)$ where $k'_i$ is produced by a sequence of $n$ updates. The schema for the relational encoding is $Sch_{End(T)}(T, R) = Sch(R) \triangleright ID_{rel}(Sch^{u_{n+1}}(T, R) \triangleright Sch^{v_{n+1}}(T, X_1) \times \ldots \times Sch^{v_{n+1}}(T, X_m) \triangleright U_{n+1} \triangleright UC$. Cases 1) and 3) can be distinguished from case 2) based on whether all attributes in $Sch^{v_{n+1}}(T, R)$ are null or not. In case 1) $k'_i$ is an annotation produced by less than or equal to $n$ updates and, thus, can be reconstructed based on the induction assumption. In case 2) we can construct the monomial $k_1 \times \ldots \times k_{n}$ in the same fashion as in the base case as long as it is possible to determine which attributes in $Sch^{u_{n+1}}(T, R_1) \times \ldots \times Sch^{v_{n+1}}(T, R_m)$ belong to which $Sch^{v_{n+1}}(T, R_i)$. This is possible using the query $Q$ of the insert which is encoded in $U_{n+1}$. The tuple id in $I_{T,\nu}(u)$ is reconstructed using the deterministic scheme introduced in Section 5.2.

- **Delete Case:** Let $u_{n+1} = D[\theta, T, \nu](R)$: The case for delete is analogous to the case for updates.

**Theorem 7.2** Let $T$ be a transaction. Then:

$TR(\mathbb{R}(T)) = Rel(\mathbb{R}(T))$

**Proof** We prove the theorem through induction over the number of operations in a transaction.

**Base Case:** Consider a transaction $T = u_1, c$ with one operation $u$ and $End(T) = \nu_c$ and $\nu(u_1) = \nu_u$. We treat each of the three types of update operations separately.

- **Update Case:** Let $u = U[\theta, A, T, \nu](R)$: The reenactment query $\mathbb{R}(T)$ is a $C_{T,\nu_{n+1}}(\mathbb{R}(T)) \triangleright Rel(T)$ where the two True constants are for attributes $U_{t}$ and $U_{T}$. We have to prove that if $k_i$ in $R[T](t)$ then $t_{i} = t \triangleright T' \triangleright \nu_{n+1} \triangleright Rel(T) \triangleright True$ where the two True constants are for attributes $U_{t}$ and $U_{T}$. To prove this we have to show that in the base case the query $Q$ of the insert which is encoded in $U_{n+1}$. The tuple id in $I_{T,\nu}(u)$ is reconstructed using the deterministic scheme introduced in Section 5.2.
$t' \triangleright T' \triangleright \text{End}(T') \triangleright id \triangleright t(x_{id}) \triangleright \text{True}$. Because of the crossproduct with $R_{id} \times \{(\text{true})\}$ the final result tuple will be $t \triangleright T' \triangleright \text{End}(T') \triangleright id \triangleright t(x_{id}) \triangleright \text{True} \triangleright \text{True} = t_{k_i}$.

$\Leftarrow$: Assume that $t_{k_i}$ is in the result of $T R(R^R(T'))$. Since the final operation in $T R(R^R(T))$ is a selection on $U_1$ and $U_2$ is only true in the left branch of the union in $\text{Rew}(q)$ we know that this tuple is from the left input of the union. This immediately implies that there has to exist a tuple $t' \triangleright T' \triangleright \text{End}(T') \triangleright id \triangleright t(x_{id})$ in $\text{Rew}(R[T'])$ which fulfills the condition of the update $u_1$. Thus, a summand $k_i$ corresponding to this tuple will be in $R[T](t)$.

$$u_1 = I(Q(R_1, \ldots, R_n), T, \nu)(R);$$

The reenactment query for $u_1$ is $T(R, \nu) \cup \Omega_{T, \nu_1}(Q(D[T, \nu_0]))$. The relational rewrite for $T R(R^R(T))$ is

$$\text{Rew}(R^R(T)) = q_1 \cup q_2$$

$$q_1 = (P_{\text{null}}(R), I_{D_1}(P(R))) \{(\text{Rew}(R[R_\nu]))$$

$$\times \text{Null}(I_{D_2}(P(Q) \triangleright U_1))\}$$

$$q_2 = (I_{\text{null}}(R_2), I_{D_1}(P(R)), I_{D_2}(P(Q))) \{\text{Rew}(Q))$$

$$\times \text{Null}(I_{D_1}(P(Q) \triangleright U_1))\}$$

Since $U_1$ is true in the right input of the union and false in the left input, because of $\text{Null}(I_{D_2}(P(Q) \triangleright U_1))$, any result returned by $T R(R^R(T))$ originates in the right input. It remains to be shown that $\text{Rew}(Q)$ produces the correct result, because the additional version annotation attributes ($U_1$ and $U_2$), derived in the same fashion as for update, are true. Note that for queries the rewrite rules are the rewrite rules introduced in Perm which were shown to derive a relational encoding of provenance polynomials except that a snapshot of relations is accessed and that the provenance attributes for a relation $R$ contain additional attributes $X_{id}$, $V$, and $Id$. Since these additional attributes are not treated any different from the other provenance attributes of $R$ in the rewrite rules, the correctness of $\text{Rew}(Q)$ follows from the correctness of the Perm rewrite.

$u = D(\theta, T, \nu)(R)$: analog to the case for updates.

**Inductive Step:** Let $T = u_1, \ldots, u_{n+1}, c$ and assume that the relational rewrite for any transaction of length up to $n$ is correct. We now show that the same holds for $T$. We distinguish between three cases based on whether the last operation is an update, insert, or delete. We need to show that the new parts of annotations added by $u_{n+1}$ under $K'$-relational semantics are correctly encoded and that the correct encoding of annotations in the input is preserved in the output if these annotation occur in an annotation produced by $u_{n+1}$.

$u_{n+1} = U(\theta, A, T, \nu)(R)$: Each summand $k_i$ in an annotation $k = \{R[T](t)\}$ for a tuple $t$ is either of the from

$$C_{T, \nu_T(u_{n+1})}^{\text{id}}(k_i')$$

where $k_i'$ is an annotation produced by any of the previous updates of $T$ that affected $R$ or a summand in an annotation on a tuple in $R[Start(T)]$ (in case the annotated tuple in the input of $u_{n+1}$ fulfills the condition the update $u_{n+1}$ and, thus, was updated) or

$$C_{T, \nu_T(u_{n+1})}^{\text{id}}(k_i)$$

The first case is analog to the base case for updates with the only exception that the relational encoding of $k_i'$ is more complex. However, observe that the proof of the base case does not make use of the properties of $k_i'$. Thus, the relational encoding of all summands that belong to the first type is correct in $T R(\text{Rew}(T))$. In the second case, observe that $k_i$ would occur as a summand in an annotation on tuple $t$ in $T' = u_1, \ldots, u_{n+1}$ and according to the induction hypothesis the encoding of $k_i$ is correct in the input of $u_{n+1}$. Let $t_{k_i}$ be this relational encoding. It remains to be shown that the relational translation of $R^R(u_{n+1})$ propagates this encoding to its output assuming that $t$ does not fulfill the update’s condition (otherwise $k_i$ would not occur in the annotation of $t$ in $R[T]$). Since $t$ does not fulfill $\theta$, $t_{k_i}$ would be present in the right input of the union in $\text{Rew}(q)$ (where $q$ is the union in the reenactment query for $u_{n+1}$ as in the proof of the base case for updates). Tuple $t$ fulfills $\neg \theta$ and, thus is extended with $(false, true)$ (attributes $U_{n+1}$ and $U_c$). That is, as was to be proven $T R(R^R(T))$ returns $t_{k_i} \triangleright false \triangleright true$.

$u = I(Q(R_1, \ldots, R_n), T, \nu)(R)$: Consider a summand $k_i$ in an annotation $k = \{R[T](t)\}$ for a tuple $t$. Again, we have to distinguish between two cases: summands produced by the insert and summands that are already present in the previous version of relation $R$ before executing the insert. The correctness of the first case follows based on the proof for the base case if for $k_i = C_{T, \nu_T(u_{n+1})}^{\text{id}}(k_{i_1} \times \ldots \times k_{i_n})$ we have that for each $k_{i_j}$ the relational encoding of $k_{i_j}$ in the version of relation $R_i$ before execution of the insert is propagated correctly by the relational translations of the reenactment query for $u_{n+1}$. This is proven analog to the base case based on the correctness of the Perm
rewrites for regular provenance polynomials and the observation that the propagation for MV-semiring elements only differs in the propagated attributes and these attributes are not affected by the rewrite rules.

The second case is trivial since the reenactment query for an insert unions the relational encoding of the previous version of relation $R$ before the insert with the result of the insert’s query. Thus, any tuple in the previous version of $R$ is propagated by extending it with $(false, true)$ (attributes $U_{n+1}$ and $U_C$).

$u = D[\theta, T, \nu](R)$: The case for delete is analog to the case for updates.
